1. Introduction

Boron, the fifth element in the periodic table, is the only electron-deficient nonmetallic element. It has a great affinity for oxygen. In nature boron always occurs in the oxygenated state, mainly as borates. The structure of these covalently bonded boron – oxygen compounds consists of either planar BO_3 units with 120° between bonds or tetrahedral BO_4 units. In addition, boron is the only light element having two abundant isotopes, ^{10}B (18.8 %) and ^{11}B (81.2 %).

Boron is found in the earth's crust at an average concentration of about 10 ppm. Large deposits of commercially valuable boron minerals are only found in a few localities, usually sites of earlier intense volcanic activity. There are about 150 known boron-containing minerals [1], and of these only tincal, colemanite, ulexite, kernite, probertite, and szaibelyite are of significant commercial importance (Table 1).

The Arabic word for borax, baurach, is found in old manuscripts from ancient Persia and Arabia dating 2000 years ago. Tincal, the mineral name for borax decahydrate, derives from tincana, the Sanskrit word for borax. Borates were known before Babylonian times to be useful as a flux for welding gold and have been found in enamels from China as early as 300 B.C. At the end of the 13th century Marco Polo brought borax from Mongolia to Europe. This became the primary European source for use as a soldering and enameling agent. In Turkey borates have been known since the 13th century. In 1772 boric acid or sassolite was discovered in hot springs located in Tuscany, Italy. About 1836, borates were discovered in Chile and Argentina, and these deposits quickly became the major source of world borates until the end of the century. By 1864 borates had been discovered in California and Nevada (USA).

The large sodium borates deposit of United States Borax & Chemical Corp. was discovered in California in 1913. Production began in 1927, and this has become the principal world source of refined sodium borates and boric acid. Reserves include tincal, kernite, and ulexite. American Borate Corp. near Death Valley in California produces colemanite and ulexite. Kerr McGee Chemical Corp. extracts borates from brines located at Searles Lake in California.

Reserves and production of borates in Turkey are operated by Etibank, a government con-

trolled corporation [2]. A large sodium borates deposit found at Kirka has reserves of tincal and kernite, estimated at 500×10^6 t, which are very similar to the deposit in California. The Kirka reserve is by far the largest known borate deposit. Much smaller deposits of colemanite are found at Bigadic, Keatelek, and Hisarcik. Ulexite is also found at Bigadic. Colemanite and ulexite are the principal minerals mined.

Both tincal and ulexite are found in Argentina and ulexite is found in Peru. Borate reserves in the Soviet Union are found in the Inder district of Kazakhstan, and consist principally of szaibelyite and hydroboracite. Although production in the USSR is relatively small, reserves are believed to be extensive. Ascharite, a magnesium borate, is the source of most borates produced in the Peoples Republic of China.

2. Boric Oxide

Boric oxide (B_2O_3) [*1303-86-2*], M_r 69.62, exists as vitreous glass and as two crystallineforms. The *vitreous form* is a colorless, hard, tough, glasslike solid, commonly prepared by dehydration of boric acid. The most common crystalline B_2O_3 has a *hexagonal* or *α-form* and is crystallized at 200 – 250 °C at ambient pressure. A less common *monoclinic β-form* can be crystallized at 4000 MPa and 600 °C [3].

2.1. Physical Properties

Vitreous B_2O_3 is difficult to obtain in a completely anhydrous state even when heated at > 1000 °C [4]. Many physical properties of B_2O_3 are sensitive to small amounts of residual water. Very dry B_2O_3 can be prepared by heating at 200 – 400 °C in high vacuum [5]. Vitreous B_2O_3 softens between 325 and 450 °C and the melt is still quite viscous at > 1000 °C. The dynamic viscosity of the melt is:

t, °C	300	400	500	600	700
η, Pa · s	4.4×10^8	1.6×10^8	3900	480	85
t, °C	800	900	1000	1100	
η, Pa · s	26	12	7.4	4.3	

The density (ϱ) of the vitreous form is dependent on both its thermal history and moisture content. Commercial boric oxide has a density of 1.84 g/cm^3, whereas very dry B_2O_3 has a density of 1.82 g/cm^3 at 20 °C. The density at high temperature has been investigated [6]. Annealed B_2O_3 has a greater density compared to rapidly cooled melt (1.53 g/cm^3 when quenched from 1000 °C), implying a higher degree of molecular order in the annealed material [7]. The heat of formation of amorphous B_2O_3 glass is 1260 kJ/mol [8].

Crystalline hexagonal or α-form, *mp* 450 °C, ϱ 2.42 – 2.46 g/cm^3; monoclinic or β-form, *mp* ca. 510 °C [9], ϱ 2.95 g/cm^3; the β-form is much more resistant to attack by water and dilute HF than the α-form.

The heat of formation for crystalline B_2O_3 is 1274 kJ/mol. Its heat capacity increases with temperature from 1.05 J g^{-1}K^{-1} at 100 °C to 1.82 J g^{-1}K^{-1} at 275 °C [10]. The heat of vaporization is calculated as 391.6 kJ/mol at 1800 °C [11], and the heat of sublimation is 431.4 kJ/mol at 25 °C [12]. The electrolytic conductivity (κ) is only 5×10^{-4} S/cm at 300 °C [13]. The refractive index (n_D) varies between 1.4502 and 1.4633, depending on the thermal history [5]. The vapor pressure of B_2O_3 melt is [9], [14]:

t, °C	1163	1270	1673	1810	2000	2146
$p_{B_2O_3}$, kPa	0.0005	0.005	1.5	5.7	24	80

The vapor composition (by mass spectrometry) is predominantly $B_2O_3^+$ with about 7 % each of $B_2O_2^+$ and BO^+ and 2 % B^+. Boric oxide has been observed to be more volatile in steam than in a dry atmosphere. The green color of B_2O_3 in a flame has been attributed to BO_2 as the emitting species.

Historically there has been considerable controversy over the *molecular structure* in liquid and vitreous B_2O_3. The structure is believed to consist of a random network of trigonal BO_3 units and boroxol rings with short-range localized order. There is disagreement over the relative amounts of these two structural units. A summary of the structural data has been reported [15].

Boroxol

Trigonal BO_3

Apparently the structure interpretation can be influenced by the presence of residual moisture.

2.2. Chemical Properties

Molten B_2O_3 is corrosive to most metals and alloys at temperatures exceeding 1000 °C. This is because of the fluxing character of B_2O_3, which keeps the metal surface clean and vulnerable to attack by oxygen in the air. Molybdenum and nickel alloys are resistant to corrosion below 1000 °C, whereas silicon carbide is resistant above 1200 °C.

Reduction of B_2O_3 at high temperatures by aluminum, magnesium, or alkali metals produces $B_{12}O_3$ and other boron suboxides. Above 900 °C carbon reacts with B_2O_3 in a nitrogen atmosphere to form boron nitride, which can also be made by reacting B_2O_3 with ammonia at 600 – 900 °C.

Vitreous B_2O_3 reacts exothermically with 3 mol of water to form crystalline boric acid, with a heat of hydration of − 76.5 kJ/mol [16]; heat of hydration of crystalline B_2O_3 is − 58.2 kJ/mol. Above 135 – 140 °C boric oxide reacts with water to form metaboric acid.

Sodium hydride reacts with B_2O_3 at 330 – 350 °C to give sodium borohydride in about 60 % yield [17]. Reaction of either B_2O_3 or boric acid with anhydrous H_2SO_4 or oleum forms the acid $HB(HSO_4)_4$ [18].

2.3. Production

High-purity B_2O_3 (99 %) is made by fusing refined boric acid. A 96 % grade of B_2O_3 is made commercially by fusing a mixture of sodium tetraborate plus sulfuric acid at 800 °C. Two molten layers are formed, an upper layer of boric oxide and a lower layer of sodium sulfate. The molten B_2O_3 layer is separated and cooled on chill rollers. The resulting glass is ground, sized, and packaged in moisture-proof containers. The product B_2O_3 contains 3 – 4 % sodium sulfate.

Boric oxide can also be prepared by thermal decomposition of ammonium pentaborate, $NH_4B_5O_8 \cdot 4H_2O$ [*12229-12-8*], at 500 – 900 °C and through direct reaction of boron with oxygen [19].

3. Boric Acid

Boric acid can be viewed as a hydrate of boric oxide and exists both as a trihydrate, orthoboric acid ($B_2O_3 \cdot 3H_2O$ or H_3BO_3) [*10043-35-3*], and asa monohydrate, metaboric acid ($B_2O_3 \cdot H_2O$ or HBO_2) [*13460-50-9*]. Only the more stable orthoboric acid form is of commercial importance and is usually referred tosimply as boric acid. The terms "pyroboric acid" and "tetraboric acid" are sometimes encountered in the literature, but these acids do not actually exist as solid-phase compounds.

3.1. Physical Properties

Boric acid crystallizes from an aqueous solution as odorless, white, waxy platelets. Crystalline orthoboric acid (*mp* 170.9 °C, heated in a closed space) is monoclinic, having a sheet lattice structure. Sheets consist of coplanar $B(OH)_3$ molecules linked by hydrogen bonds. These sheetlike layers are held together only by van der Waals forces. This allows easy cleavage into flakes which feel slippery.

The three known crystalline modifications of metaboric acid are shown in the $B_2O_3-H_2O$ solubility phase diagram (Fig. 1) [20]. Orthoboric acid slowly dehydrates at 100 – 130 °C to form flaky crystals of orthorhombic HBO_2 (III) (α-form, *d* 1.784, *mp* 176 °C). After disappearance of the residual H_3BO_3 at temperatures up to 160 °C, a coarsely crystalline monoclinic HBO_2 (II) (β-form, *d* 2.044, *mp* 201 °C) is formed. At yet higher temperatures (200 – 250 °C) a highly viscous liquid is formed from which cubic HBO_2(I) (γ-form, *d* 2.486, *mp* 236 °C) slowly crystallizes. With about 1 % moisture remaining, HBO_2 (I) acts as seed for crystallization of hexagonal (α) boric oxide. The structures of these metaborate forms range from all trigonal borons in HBO_2 (III), to one-third tetrahedral borons in HBO_2 (II), to all tetrahedal borons in HBO_2 (I).

The solubility of boric acid in water is increased by addition of salts, such as KCl, KNO_3, RbCl, K_2SO_4, and Na_2SO_4, whereas addition of LiCl, NaCl, and $CaCl_2$ tends to lower the solubility.

Boric acid behaves as a weak acid in aqueous solutions, pK_a of 9.23 at 25 °C [21]. As

shown in Table 2, pH decreases as concentration increases. This is because of formation of trimeric and tetrameric species. The pH also increases with temperature. The solubility of boric acid in water is shown in Table 3.

Figure 1. Solubility diagram for the system $B_2O_3-H_2O$.

The solubility of boric acid in many organic solvents is shown in Table 4. Boric acid is particularly soluble in polyhydric alcohols capable of forming complexes. Normally, boric acid is too weak an acid to titrate directly. Use of a polyhydric complexing agent, such as mannitol [*69-65-8*], enhances the acidity of boric acid sufficiently to allow accurate titration using phenolphthalein as the indicator.

The vapor pressure of boric acid is primarily due to water from dehydration equilibria. Vapor below 160 °C is composed of water and boric acid molecules. At higher temperatures, HBO_2 is also found in the vapor phase, and above 940 °C $(HBO_2)_3$ becomes significant [22].

Boric acid is volatile with steam. Distillate from a boiling saturated solution contains about 0.18 % of boric acid [23]. Boric acid is particularly volatile from concentrated solutions made acidic by strong acids. The volatile loss from low molecular mass alcohol solutions can be attributed to ester formation.

3.2. Chemical Properties

Boric acid reacts with strong bases to form metaborate ion, $B(OH)_4^-$, and with alcohols to form borate esters. Boric acid reacts with fluoride ion to form tetrafluoroboric acid and with hydrofluoric acid to form trifluoroboric acid $H(F_3BOH)$, which can be distilled at reduced pressures (58.5 – 60.0 °C at 0.16 kPa) [24].

3.3. Production

Boric acid is manufactured industrially from borate minerals and brines [25]. Alkali and alkaline-earth metal borates, such as borax, kernite, colemanite, ascharite, ulexite, or hydroboracite, react with strong mineral acids to form boric acid. In the United States boric acid is made primarily from sodium borate minerals, whereas in Europe it is made from colemanite imported from Turkey. In the Soviet Union magnesium borates from the Inder region are used to make boric acid. Borates found in saline lake brine in California at Searles Lake are extracted and recovered as boric acid.

The world's largest and most modern boric acid plant was constructed by U.S. Borax in 1981 at Boron, California. Crushed kernite ($Na_2O \cdot 2\,B_2O_3 \cdot 4\,H_2O$) ore is reacted with sulfuric acid in recycled weak liquor (contains low concentration of borates) at 100 °C. Coarse gangue is separated by rake classifiers and fine particles are settled in a thickener. The boric acid strong liquor (high borate concentration) is nearly saturated with sodium sulfate. Complete solubility of sodium sulfate is maintained throughout the process by careful control of pH and temperature. The strong liquor is filtered at 98 °C and boric acid crystallized in two stages using continuous evaporative crystallizers. The temperature is dropped to 70 °C in the first stage and to 35 °C in the second. Crystals are filtered

[i] More stable above 46 °C.

and washed with progressively weaker liquor in a countercurrent fashion. The final product is dried in rotary driers and screened for packaging. Weak liquor at 35 °C, nearly saturated in sodium sulfate, is heated to 100 °C and returned to the reactor. Sodium sulfate is removed from the process as solid in gangue and in effluent from a second-stage thickener, and is pumped to sealed solar ponds. The plant has a capacity of 113000 t/a (expressed as B_2O_3).

In Europe boric acid is produced from crushed colemanite ($2CaO \cdot 3B_2O_3 \cdot 5H_2O$) ore by reaction with sulfuric acid at 90 °C. Byproduct gypsum ($CaSO_4$) and gangue are fil-

tered and the hot mother liquor cooled to crystallize boric acid. The weak liquor is recycled to the reactor.

Magnesium borate ores, primarily of ascharite (szarbelyite, $2\,MgO \cdot B_2O_3 \cdot H_2O$), and hydroboracite ($CaO \cdot MgO \cdot 3\,B_2O_3 \cdot 6\,H_2O$), are finely ground and decomposed to boric acid with sulfuric acid at 95 °C. Insoluble gypsum and gangue are filtered and the mother liquor is cooled to 15 °C to crystallize boric acid. The weak liquor is nearly saturated in magnesium sulfate ($MgSO_4 \cdot 7\,H_2O$), which is crystallized by concentration of the liquor at elevated temperature; the concentrated liquor is then recycled to the reactor.

Datolite ($2\,CaO \cdot B_2O_3 \cdot 2\,SiO_2 \cdot H_2O$) is the most common silicoborate mineral. Ore containing 5 % B_2O_3 is finely ground and digested with sulfuric acid. Silica in the mother liquor is coagulated upon heating to 95 °C. The resulting boric acid solution is nearly free of silicic acid.

At Searles Lake, California, borax is found in brine at a concentration of about 1.5 % (expressed as anhydrous borax); a number of other salts are also present. A process using liquid–liquid extraction is used to separate borax selectively from brine. Borax is extracted into a water-insoluble solvent, such as kerosene, by use of an aromatic polyol that efficiently complexes the borate ion, e.g., 3-chloro-2-hydroxy-5-isooctylbenzenemethanol [*31567-74-5*]. The organic phase is isolated and acidified with sulfuric acid, giving an aqueous solution of boric acid and sodium sulfate. After concentrating by evaporation, the liquor is cooled to crystallize boric acid.

3-Chloro-2-hydroxy-5-isooctylbenzenemethanol

4. Aqueous Borate Solutions

Dilute borate solutions contain only monomeric species. Solutions of boric acid below 0.1 M contain monomeric boric acid molecules, $B(OH)_3$, and solutions of metaborate salts contain monomeric metaborate ions, $B(OH)_4^-$. Solutions made from mixtures of boric acid and metaborate salts contain a mixture of $B(OH)_3$ molecules and $B(OH)_4^-$ ions.

Polymeric borate anions form in more concentrated borate solutions. In addition to monomeric $B(OH)_3$ and $B(OH)_4^-$, concentrated borate solutions contain the polyions $B_3O_3(OH)_4^-$, $B_3O_3(OH)_5^{2-}$, $B_5O_6(OH)_4^-$, and $B_4O_5(OH)_4^{2-}$ (Fig. 2). These polyion species are all in rapid dynamic equilibrium and their distribution is dependent on the $Na_2O - B_2O_3$ molar ratio, temperature, and borate salt concentration, but is essentially independent of the cation [26].

The pH of borate salt solutions varies with both concentration (see Table 2) and temperature as a consequence of these polyions. At the isohydric point the pH value is independent of borate concentration. This occurs at a pH of 8.9 and a $Na_2O - B_2O_3$ molar ratio of 0.41 for a sodium borate solution. Borate solutions with a $Na_2O - B_2O_3$ molar ratio less than 0.4 become more acidic at higher concentrations, whereas solutions with a $Na_2O - B_2O_3$ molar ratio greater than 0.4 become more alkaline with increasing concentration (Fig. 3). Borax, with a $Na_2O - B_2O_3$ molar ratio of 0.5 makes an excellent buffer solution.

Figure 2. Distribution of borate polyanion species in aqueous solution:
B_3^- = $B_3O_3(OH)_4^-$,
B_3^{2-} = $B_3O_3(OH)_5^{2-}$,
B_5^- = $B_5O_6(OH)_4^-$,
B_4^{2-} = $B_4O_5(OH)_4^{2-}$ [20]

Figure 3. pH Values in the system $Na_2O-B_2O_3-H_2O$ at 25 °C [27]

5. Sodium Borates

The lack of a uniform system of nomenclature for naming metal borate salts has led to ambiguities in the past. Today metal borates are most commonly described by an empirical formula with the number of cations and boron atoms in the simplest stoichiometric units. The descriptive name is derived from this formula. In addition, an oxide formula is also in common use with the derived portions of metal oxide, boric oxide, and water in the simplest molar ratio. Many metal borates are also described using the mineral name, e.g., tincal for borax, $Na_2B_4O_7 \cdot 10\,H_2O$. Although useful for cataloging metal borates these formulas give no indication of the molecular structure of the borate anion found in the solid crystals. The solubilities of the borates described in this chapter are summarized in

Table 3. Of the sodium borates discussed, only borax decahydrate (Section 5.1) and borax pentahydrate (Section 5.2) are sold in large commercial volume.

5.1. Sodium Tetraborate Decahydrate

Sodium tetraborate decahydrate [*1303-96-4*], borax, tincal, $Na_2O \cdot 2\,B_2O_3 \cdot 10\,H_2O$ or $Na_2B_4O_7 \cdot 10\,H_2O$, crystals are odorless, white, monoclinic prisms with a relative density of 1.715. Based on the crystal structure, borax is best represented by the formula $Na_2\,[B_4O_5(OH)_4\,] \cdot 8\,H_2O$, with 2 mol of water existing as hydroxyl groups and 8 mol as water of crystallization [28]. The water in borax can be maintained at exactly 10 mol by storage in a closed container with a relative humidity produced by a solution saturated in both sucrose and salt [29].

Borax decahydrate slowly dehydrates at ambient conditions, depending on the relative humidity, to a water content of about 7 mol. The dehydration path is dependent on the thermal history of the sample [29]. Freshly crystallized borax previously heated to about 50 °C has a vapor pressure of 1.33 kPa at 19.8 °C and follows a stable dehydration path. That is, it dehydrates reversibly to borax pentahydrate at ambient temperature with a heat of dehydration of 54.17 kJ/mol. Further dehydration under vacuum produces an amorphous product containing 2 mol of water. Freshly crystallized borax decahydrate maintained below 50 °C has a vapor pressure of only 0.22 kPa at 20 °C and follows an unstable dehydration path. At ambient pressure and temperature over H_2SO_4 it undergoes irreversible dehydration leading directly to the amorphous hydrate (2 mol H_2O), bypassing borax pentahydrate. This hydrate can rehydrate first to borax pentahydrate and then to borax decahydrate.

Borax heated in a closed container melts in its own water of hydration at about 60 °C. Borax loses 5 mol of water by heating from 50 to 100 °C and loses an additional 3 mol up to 160 °C (determined by thermal gravimetric analysis). The remaining 2 mol of water are slowly lost during heating to about 400 °C. Anhydrous borax fuses at 742 °C forming a clear glass.

Rapid heating of borax decahydrate causes puffing [30]. Puffed borax consists of small glassy hollow spheres with a void volume as high as 90 % and a bulk density of about 0.07 g/cm^3.

Borax has a heat of formation of − 6264.3 kJ/mol [31], and a specific heat of 1.611 kJ kg^{-1}K^{-1} at 25 – 50 °C [32].

Borax decahydrate crystallizes from aqueous solution below 60.8 °C, the decahydrate – pentahydrate transition temperature (Fig. 4). This transition temperature is lowered by addition of either boric acid or sodium hydroxide [33]. In a solution saturated with sodium sulfate this transition temperature drops to 49.3 °C; with sodium chloride it drops to 39.6 °C; and when saturated with sodium chloride and potassium sulfate it drops to 35.5 °C. The solubility of borax in organic solvents is shown in Table 4.

The pH value of a borax solution increases slightly with increasing concentration (Table 2), and drops slightly with increasing temperature [34].

5.2. Sodium Tetraborate Pentahydrate

Sodium tetraborate pentahydrate[*12045-88-4*], tincalconite, $Na_2O \cdot 2\,B_2O_3 \cdot 5\,H_2O$ or $Na_2B_4O_7 \cdot 5\,H_2O$, crystals have rhombohedral symmetry and resemble octahedra; their relative density is 1.880. This pentahydrate has the same polyanion structure as borax decahydrate and is best represented by the formula $Na_2\,[B_4O_5\,(OH)_4] \cdot 3\,H_2O$, with 3 mol of water of crystallization and 2 mol of water existing as hydroxyl groups. Pure borax pentahydrate actually contains 4.75 mol rather than 5.0 mol of water because of apparent vacancies in the crystal structure [35].

Borax pentahydrate rapidly crystallizes from aqueous solution above 60.8 °C (Fig. 4). Solid pentahydrate in equilibrium with its saturated solution is metastable to kernite at all temperatures above 58.2 °C. When a solution saturated with borax pentahydrate is heated for one day or more, kernite crystals slowly form [36]. The solubility of tincalconite in organic solvents is shown in Table 4.

From thermogravimetric analysis 3 mol of water are lost on heating borax pentahydrate at 160 °C. The last 2 mol are slowly lost up to about

Figure 4. Solubility versus temperature curves for borate hydrates [33].

400 °C. Pentahydrate dehydrates reversibly to an amorphous dihydrate on heating at 80 °C and 0.3 kPa pressure or at 140 °C in air.

Like borax decahydrate, borax pentahydrate puffs when rapidly heated [30].

The heat of formation for borax pentahydrate is $-4\,784$ kJ/mol [31] and the specific heat is $1.318\,\mathrm{kJ\,kg^{-1}K^{-1}}$ [32].

Production. Refined borates are almost exclusively produced as a sodium salt, with a minor amount of potassium salt and even smaller amounts of lithium and ammonium salts.

Sodium borate ore consisting primarily of tincal and clay is crushed, mixed with Trona, and dissolved in weak liquor at 100 °C. The coarse gangue is separated on a screen and strong liquor and fine insolubles are transferred to a primary thickener. Clarified strong liquor is used to produce borax pentahydrate in continuous vacuum crystallizers at a temperature above the borax penta – decahydrate transition temperature of 60.8 °C. Borax decahydrate product crystallizes below this transition temperature. Crystals are filtered using a continuous centrifuge and dried in rotary driers. Borax crystals are washed with a weak boric acid solution leaving a very thin surface coat of pentaborate, which inhibits caking. Thickened underflow from the primary thickener is washed in a countercurrent fashion through four thickener stages with progressively weaker liquor in each stage. Fresh water is added to the last stage thickener. Liquid effluent is pumped to sealed solar ponds. The plant B_2O_3 capacity is 2030 t/d.

Calcium and sodium calcium borate ores were once a major source for borax production, but since the discovery of the high-grade borax deposit in California they are of less importance. Ulexite ($Na_2O \cdot 2\,CaO \cdot 5\,B_2O_3 \cdot 6\,H_2O$) is preferred over calcium borates and borosilicates because less alkali is required and less insoluble calcium salts are produced. Ulexite (ca. 38 % B_2O_3), which is finely ground and prefer-

ably calcined at 390 °C, is heated with aqueous sodium carbonate and sodium hydrogen carbonate to a near boil for several hours. The insoluble calcium carbonate is filtered and borax crystallized from the mother liquor in about 91 – 96 % yield.

Borax is recovered from upper lake brines by Kerr McGee at Searles Lake in California by heating and evaporating water to precipitate NaCl, Na_2CO_3, and Na_2SO_4. The hot liquor, which is nearly saturated in KCl, is then rapidly cooled in a vacuum crystallizer to precipitate KCl. The cool mother liquor, which is supersaturated with borax, is treated with $NaHCO_3$ to crystallize crude borax pentahydrate. This crude material is washed with brine and recrystallized as either borax deca- or pentahydrate. In a carbonation process borax is recovered from the lower brines by treatment with purified flue gas, causing $NaHCO_3$ to precipitate. The filtrate is neutralized with raw brine and cooled to crystallize crude borax.

A very pure grade of borax can be produced by reacting refined boric acid with hot NaOH solution and crystallizing the resulting borax.

5.3. Anhydrous Sodium Tetraborate

Anhydrous sodium tetraborate [*1330-43-4*], anhydrous borax, $Na_2O \cdot 2\,B_2O_3$ or $Na_2B_4O_7$. Fused borax forms an amorphous glass when rapidly cooled (density 2.36 g/cm^3). When slowly cooled orthorhombic crystals (α-form) are obtained. A β- and γ-form also exist [37]. The α-form is the most stable form with a congruent melting point at 742.5 °C. Its heat of formation has been calculated as − 3290 kJ/mol [38], and its vapor pressure is 0.73 kPa at 1200 °C, 1.73 kPa at 1250 °C, and 3.39 kPa at 1300 °C. Anhydrous borax dissolves more slowly in water than hydrated forms, giving off a large amount of heat; heat of hydration is 161 kJ/mol. The integral heat of solution in water to give a 2.5 wt % solution is − 192.6 J/g at 51.5 °C and 190.5 J/g at 60 °C. The solubility in several organic solvents is shown in Table 4.

The melt attacks most refractories at 800 °C. Many metal oxides are soluble in borax glass giving characteristic colors. Anhydrous borax reacts with carbon at 1200 °C in the absence of oxygen to form B_4C_3 and Na_2C_2, and reacts with metallic sodium to form elemental boron.

Production. Anhydrous borax is produced commercially by dehydration of hydrated sodium tetraborates in large fusion furnaces to form a borate glass. Anhydrous borax melts at 742 °C and this melt readily supercools to an amorphous glass. A crystalline form can be obtained by prolonged annealing or by seeding. The melt is very corrosive to furnace refractories and methods have been devised to keep borax away from the furnace walls [39].

5.4. Sodium Metaborate Tetrahydrate

Sodium metaborate tetrahydrate [*10555-76-7*], $Na_2O \cdot B_2O_3 \cdot 8\,H_2O$ or $NaBO_2 \cdot 4\,H_2O$, crystals are triclinic with a density of 1.743 g/cm^3. From X-ray studies the structure is best represented by the formula $NaB(OH)_4 \cdot 2\,H_2O$, containing $B(OH)_4^-$ ions [40]. Crystals begin to melt in their own water of hydration at 53.5 °C. At low humidity water is lost forming the dihydrate. By differential thermal analysis (DTA) 1 mol of water is lost at 130 °C, a second at 140 °C, and a third at 280 °C; the remaining water is slowly lost up to 800 °C. Heat of hydration is 52.51 kJ/mol.

Sodium metaborate tetrahydrate is the stable solid phase in contact with its saturated solution between 11.5 and 53.6 °C. Solutions are easily supersaturated. Both crystals and solutions absorb carbon dioxide from air forming borax and sodium carbonate. The pH of aqueous solutions increases with concentration (see Table 2).

Production. Sodium metaborate tetrahydrate is made commercially by crystallization (< 30 °C) from a solution containing borax and a slight excess of sodium hydroxide.

A solution of sodium metaborate, prepared from borax pentahydrate and sodium hydroxide, is reacted with hydrogen peroxide on a large commercial scale to produce sodium perborate tetrahydrate, $NaBO_3 \cdot 4\,H_2O$ or $Na_2O \cdot B_2O_3 \cdot 2\,H_2O_2 \cdot 6\,H_2O$, containing about 10 wt % available oxygen. Sodium perborate crystallizes in transparent monoclinic crystals, which are comparatively stable in air [41]. Its

aqueous solution slowly decomposes; decomposition is accelerated by catalysts or elevated temperature.

Perborate anion

5.5. Sodium Metaborate Dihydrate

Sodium metaborate dihydrate [*16800-11-6*], $Na_2O \cdot B_2O_3 \cdot 4\,H_2O$ or $NaBO_2 \cdot 2\,H_2O$, crystals are triclinic with a relative density of 1.909. The dihydrate is crystallized from aqueous solutions at 53.6 – 105 °C. When solutions are cooled rapidly very small needles, which are difficult to filter, form. Large platelike crystals form over several days during slow crystallization at 54 – 80 °C [42].

Sodium metaborate dihydrate slowly loses water at ambient temperatures and becomes sticky when heated. The heat of dehydration is 58.2 kJ/mol [43]. A monohydrate can be produced by dehydrating the dihydrate or by crystallization from highly basic solutions above 40 °C. Anhydrous sodium metaborate, $NaBO_2$, formed by heating to 350 °C, is very hygroscopic. At 966 °C it melts forming a clear glass.

5.6. Sodium Pentaborate Pentahydrate

Sodium pentaborate pentahydrate [*12046-75-2*], sborgite, $Na_2O \cdot 5\,B_2O_3 \cdot 10\,H_2O$ or $NaB_5O_8 \cdot 5\,H_2O$, crystals are triclinic with a density of 1.713 g/cm^3. The heat capacity, heat content, and entropy and other thermal functions have been reported from 0 to 345 K [44].

Sodium pentaborate is stable in contact with its saturated solution between 2 and 59.5 °C. Below 2 °C borax forms, and above 59.5 °C, $2\,Na_2O \cdot 9\,B_2O_3 \cdot 11\,H_2O$, Taylor's borate (*d* 1.903), slowly crystallizes if seeds are present. Supersaturated aqueous solutions of Taylor's borate easily form up to the boiling point. Still lower hydrates of 4, 2, 1, and 0 mol of water crystallize at temperatures above 100 °C under pressure [45].

Production. Sodium pentaborate can be made by gradually heating borax and boric acid (1 : 6 molar ratio) in a rotary drier from 30 to 66 °C [46]. It is also made by spray drying a borate solution of the appropriate composition.

5.7. Disodium Octaborate Tetrahydrate

Disodium octaborate tetrahydrate [*12280-03-4*], $Na_2O \cdot 4\,B_2O_3 \cdot 4\,H_2O$ or $Na_2B_8O_{13} \cdot 4\,H_2O$, is a spray-dry product. It is an amorphous solid, and is sold under the trade name Polybor; boron content is high (67.1 % B_2O_3), as is solubility in water. It is easily dissolved in cool water to give supersaturated solutions of considerable concentration. Above 60 °C, concentrated solutions become quite viscous. In aqueous solution the pH decreases with concentration (Table 2).

5.8. Disodium Tetraborate Tetrahydrate

Disodium tetraborate tetrahydrate [*12045-87-3*], kernite, $Na_2O \cdot 2\,B_2O_3 \cdot 4\,H_2O$ or $Na_2B_4O_7 \cdot 4\,H_2O$, forms monoclinic crystals (*d* 1.908) consisting of infinite linear chains of the polyanion $[B_4O_6(OH)_2]^{2-}{}_n$ made up of fused six-membered rings [47]. The heat of formation at 24 °C is − 4489.0 kJ/mol [31]. Crystal cleavage forms long fibrous needles.

Borax pentahydrate is metastable to kernite when in contact with its saturated aqueous solution above 58.2 °C (see Fig. 4). However, the rate of crystallization and of dissolution of kernite is very slow compared to borax pentahydrate. Calcined kernite dissolves at a considerably faster rate compared to the tetrahydrate.

Kernite hydrates irreversibly to borax decahydrate under ambient conditions. It dehydrates reversibly to the dihydrate, metakernite, over P_2O_5 in a vacuum or by heating at 100 – 120 °C. Further dehydration by heating to 190 °C causes irreversible dehydration forming an amorphous monohydrate. Rehydration of this monohydrate forms borax penta- and decahydrate.

Heating kernite to 180 °C results in the loss of 3 mol of water (DTA). The last mole of water is slowly lost up to 400 °C.

6. Other Metal Borates

6.1. Calcium and Calcium Sodium Borates

Calcium and calcium sodium borates are next to sodium borates in commercial importance. This includes the minerals colemanite, ulexite, and probertite.

Colemanite [*12291-65-5*] , $2\,CaO \cdot 3\,B_2O_3 \cdot 5\,H_2O$ or $Ca_2B_6O_{11} \cdot 5\,H_2O$, is the most widely occurring calcium borate mineral. Crystals of pure colemanite are monoclinic with a relative density of 2.42 and heat of formation of $-3\,469$ kJ/mol. Its crystal structure is represented by the formula $Ca_2B_6O_8(OH)_6 \cdot 2\,H_2O$ and is made up of polymeric chains of $[B_3O_4(OH)_3]^{2-}$ anions [48]. The solubility in water at 25 °C is about 0.18 wt % as B_2O_3 and 0.38 wt % at 100 °C. At about 350 °C, colemanite decrepitates violently losing all its water of hydration.

Ulexite [*1319-33-1*] , $Na_2O \cdot 2\,CaO \cdot 5\,B_2O_3 \cdot 16\,H_2O$ or $NaCaB_5O_9 \cdot 8\,H_2O$, forms triclinic needles with a density of 1.955 g/cm^3. The crystal structure consists of discrete pentaborate rings and is represented by the formula $NaCaB_5O_6\,(OH)_6 \cdot 5\,H_2O$ [49]. By DTA ulexite dehydrates losing 4 mol of water at 70 – 90 °C, and another 8 mol between 100 and 120 °C; the remaining water is gradually lost up to about 400 °C.

The solubility of ulexite in water is about 0.49 wt % as $NaCaB_5O_9$ at 25 °C. Calcination at 200 – 500 °C increases the solubility to 9 – 13 g/L [50].

Ulexite can be *prepared* by reacting borax, calcium metaborate, and water at 20 °C for 119 d or at 40 °C for 60 d [36]. Also moistened probertite heated at 80 – 100 °C forms ulexite in about four weeks [51].

Probertite [*12229-14-0*] , $Na_2O \cdot 2\,CaO \cdot 5\,B_2O_3 \cdot 10\,H_2O$ or $NaCaB_5O_9 \cdot 5\,H_2O$, exists as monoclinic crystals with a density of 2.14 g/cm^3. It has a crystal structure of $NaCaB_5O_7\,(OH)_4 \cdot 3\,H_2O$ and is made up of pentaborate rings linked in polymeric chains [49]. Probertite is a commonly found scale in borax refineries. By DTA 2 mol of water are lost at about 100 °C, 4 mol more between 100 and 180 °C, and the last 4 mol are slowly lost up to 400 °C. Probertite can be *prepared* by heating borax and calcium metaborate for 8 d at 105 °C [6].

6.2. Lithium, Potassium, and Ammonium Borates

Borates of lithium, potassium, and ammonium are of much smaller commercial volume than those described in Section 6.1.

6.2.1. Lithium Borates

Lithium metaborate octahydrate [*41851-38-1*] , $Li_2O \cdot B_2O_3 \cdot 16\,H_2O$ or $LiBO_2 \cdot 8\,H_2O$, with a trigonal crystal structure, is the stable solid in contact with saturated aqueous solutions below 36.9 °C [52]. Heating the crystals causes rapid loss of 6 mol of water below 70 °C, forming orthorhombic crystals of a dihydrate, $Li_2O \cdot B_2O_3 \cdot 4\,H_2O$ or $LiBO_2 \cdot 2\,H_2O$, with a density of 1.825 g/cm^3. This dihydrate is the stable solid in contact with its saturated solution above 36.9 °C.

Lithium pentaborate pentahydrate [*37190-10-6*] , $Li_2O \cdot 5\,B_2O_3 \cdot 10\,H_2O$ or $LiB_5O_8 \cdot 5\,H_2O$, has an incongruent solubility reported as both < 37.5 °C and 40.5 °C. By DTA the solid loses 3.7 mol of water when dehydrated between 110 and 200 °C and an additional 0.8 mol are lost up to 300 °C; it becomes anhydrous at 450 °C.

Dilithium tetraborate trihydrate [*37195-62-3*] , $Li_2O \cdot 2\,B_2O_3 \cdot 3\,H_2O$ or $Li_2B_4O_7 \cdot 3\,H_2O$, has a density of 1.88 g/cm^3. When crystallized from an aqueous solution, a variety of hydrates form; when boiled the trihydrate forms [52]. Dehydration occurs at 260 °C and fusion at about 890 °C.

6.2.2. Potassium Borates

Potassium tetraborate tetrahydrate [*12045-78-2*] , $K_2O \cdot 2\,B_2O_3 \cdot 4\,H_2O$ or $K_2B_4O_7 \cdot 4\,H_2O$, is the most common of this

class. Crystals are orthorhombic, having a relative density of 1.92 and a borate anion structure similar to borax [53]. The solid loses 2 mol of water between 112 and 180 °C, with a heat of dehydration of 86.6 kJ/mol; the last 2 mol are gradually lost between 180 and 420 °C. Potassium tetraborate is more soluble than the corresponding sodium tetraborate. In contact with its saturated solution above 56 °C, it is metastable to tetrapotassium decaborate pentahydrate, $2\,K_2O \cdot 5B_2O_3 \cdot 5\,H_2O$ or Auger's potassium borate. This Auger's form is very slow to crystallize in the absence of seed. The pH value of aqueous potassium tetraborate solutions increases slightly with concentration (Table 2).

Potassium tetraborate can be crystallized from aqueous solutions of potassium hydroxide and boric acid with a $B_2O_3 - K_2O$ molar ratio of 2.0. It can also be crystallized from borax solutions by addition of potassium chloride.

Potassium pentaborate [*12229-13-9*], $K_2O \cdot 5\,B_2O_3 \cdot 8\,H_2O$ or $KB_5O_8 \cdot 4\,H_2O$, crystals are orthorhombic with a relative density of 1.74, *mp* 780 °C, and heat capacity of 330.5 J mol^{-1} K^{-1} at 298 K [44]. The heat of dehydration is 110.8 kJ/mol between 106 and 134 °C. Potassium pentaborate is less soluble than the sodium analog. The pH value of its aqueous solution decreases with concentration (Table 2). Potassium pentaborate can be crystallized from a solution of potassium hydroxide and boric acid with a $B_2O_3 - K_2O$ molar ratio of about 5.0.

6.2.3. Ammonium Borates

Ammonium pentaborate octahydrate [*12229-12-8*], $(NH_4)_2O \cdot 5\,B_2O_3 \cdot 8\,H_2O$ or $NH_4B_5O_8 \cdot 4\,H_2O$, exists in two crystalline forms: an orthorhombic α-form with a relative density of 1.567 and heat capacity of 359.4 J mol^{-1} K^{-1} at 301.2 K, and a monoclinic β-form. The crystal structure of ammonium pentaborate has the same borate ion $[B_5O_6(OH)_4]^-$ found in sodium and potassium pentaborates. Unlike diammonium tetraborate the pentaborate is very stable to ammonia loss. At 150 °C all but 2 mol of water are lost, with less than 1 % ammonia loss [27]. At 200 °C and 0.1 kPa one more molecule of water is lost with only 2 % ammonia loss.

Ammonium pentaborate tetrahydrate can be crystallized from an aqueous solution of ammonia and boric acid with a $B_2O_3 - (NH_4)_2O$ molar ratio of 5.0 [54]. To determine its solubility in water, long equilibration times are required. For this reason solubility data published prior to 1966 are suspect [55]. The pH value decreases with solution concentration (Table 2).

Diammonium tetraborate tetrahydrate [*12228-87-4*], $(NH_4)_2O \cdot 2\,B_2O_3 \cdot 4\,H_2O$ or $(NH_4)_2B_4O_7 \cdot 4\,H_2O$, has a crystal density of 1.58 g/cm^3. The solid is somewhat unstable, with an appreciable vapor pressure of ammonia at ambient pressure and temperature. It is crystallized from a solution of ammonium hydroxide and boric acid with a $B_2O_3 - (NH_4)_2O$ molar ratio of about 2.0. Aqueous solutions up to 10 % concentration have an invariant pH of 8.8. The crystal structure can be described by the formula $(NH_4)_2B_4O_5(OH)_4 \cdot 2\,H_2O$ [56].

Other metal borates are of comparatively smaller commercial volume. They are generally prepared by reacting an aqueous solution of boric acid or alkali metal borate with a metal oxide or soluble metal salt.

6.3. Zinc Borates

Several hydrates of zinc borate are known. These include $2\,ZnO \cdot 3\,B_2O_3 \cdot 3.5\,H_2O$ or ZB 2335 [*12513-27-8*], which has a crystal density of 2.69 g/cm^3 and thermal stability to dehydration up to 290 – 300 °C [57]. It is made commercially from an aqueous boric acid solution with zinc oxide above 70 °C in the presence of product zinc borate seed. An induction period of 1 – 2 h is followed by a highly exothermic reaction.

A zinc borate of composition $2\,ZnO \cdot 3\,B_2O_3 \cdot 7$ to $7.5\,H_2O$ or ZB 237 [*12429-73-1*] and [*12280-01-2*], has a crystal density of 2.44 g/cm^3, and, from its X-ray structure, has the formula $Zn[B_3O_3(OH)_5] \cdot H_2O$ [58]. Six mol of water are lost when ZB 237 is heated from 120 to 170 °C.

The nine hydrate, $2\,ZnO \cdot 3\,B_2O_3 \cdot 9\,H_2O$ or ZB 239 is made using the same conditions as for ZB 2335 below 70 °C.

The zinc borate, $ZnO \cdot B_2O_3 \cdot 2H_2O$ or ZB 112 [*27043-84-1*], is thermally stable to dehydration up to 190 °C.

Several hydrated zinc borates are of commercial importance as fire retardant and smoke suppressant agents for polymers and coatings, most notably in PVC, halogenated polyesters, and nylon. For example, ZB 2335 is sold under the trade name Firebrake ZB or ZB 2335 (U.S. Borax & Chemical Corp., USA); it has a mean particle size of 5 – 10 µm. Its high-thermal stability is an important physical property because of the high temperatures required in some plastic processing. The zinc borate ZB 112 is sold by Humphrey Chemical Co. (USA) and Storey Brothers (U.K.). In addition Humphrey sells zinc borates described as ZB 235 and ZB 237, which are prepared by dry mixing boric acid with zinc oxide. The resulting product is actually a mixture of zinc borate $2ZnO \cdot 3B_2O_3 \cdot 9H_2O$ or ZB 239 and unreacted starting materials.

7. Borate Glasses

Various alkali-metal oxides, when fused with boric oxide, form a viscous melt, which on supercooling readily forms glasses (→ Glass). Mixtures of alkali-metal borates, boric acid, and alkali-metal carbonates or hydroxides can be used. Many physical properties of these glasses have maxima and minima with increasing alkali-metal oxide to borate ratio. This has been termed the *boron anomaly,* and has been observed in such properties, as viscosity, density, thermal expansion, and heat content [41]. This anomaly has been shown to be a result of structural changes in the glass, and of the variation in proportion of tetrahedral coordination of the boron in BO_4 groups and trigonal coordination in BO_3 groups.

The viscosity of $Na_2O-B_2O_3$ and $K_2O-B_2O_3$ glass has a maximum value at 20 – 25 mol % metal oxide below 900 °C [59], and the density increases from 1.85 g/cm^3 in pure B_2O_3 to a maximum of 2.36 in mixtures containing 27 – 33 mol % metal oxide at 900 °C [60]. Maximum hardness is achieved with a composition of 25 wt % Na_2O [61]. Thermal expansion reaches a minimum up to about 13 vol % Na_2O. The index of refraction (n_D) is 1.48 at 6 vol % Na_2O, and 1.51 at 24 vol % Na_2O.

Silica is quite soluble in molten sodium borate, giving a viscous liquid. The use of boric oxide in silica glass imparts many desirable properties. Borosilicate glass approaches the desirable properties of quartz glass, except the melting range and workability of the glass melt is significantly improved. Addition of boric oxide to alkali-metal silicate glass imparts increased hardness and decreased expansivity, lowers the melting range, and increases furnace production and durability of the glass. In ceramic glass, B_2O_3 improves resistance to weathering and chemicals.

8. Quality Specifications

Product specifications for boric oxide, boric acid, and borax are listed in Tables 5 and 6.

Table 5. Specifications for commercial B_2O_3

	% Maximum	% Typical
Na	0.1	0.015
SiO_2	0.21	0.15
Al_2O_3	0.14	0.08
Fe_2O_3	0.02	0.009
CaO	0.03	0.013
MgO	0.15	0.05
SO_4	0.41	<0.20

9. Uses

The glass and ceramic industry in the United States consumes about one-half of the total domestic B_2O_3. This includes borosilicate glasses, insulation fiberglass, textile fiberglass, porcelain enamels, and ceramic glazes. The largest market is for insulation fiberglass, with typically 5 – 7 % of contained B_2O_3 from borax pentahydrate, ulexite, or probertite; whereas textile fiberglass typically has 8 – 9 % of contained B_2O_3 from boric acid or colemanite. Borosilicate glass has 12 – 15 % of contained B_2O_3 largely from borax pentahydrate. Borates are used as a flux in the manufacture of porcelain enamels and ceramic glazes. Of the total United States domestic B_2O_3 consumption, about 15 % is used in the form of boric acid and metal borates as fire retardants in cellulosic insulation and plastics; 4 % as soluble borates in agriculture as a fertilizer to amend boron-deficient soils and as a herbicide at high dosages; 10 % from borax decahydrate

Table 6. Maximum specifications for grades of boric acid, borax, and borax pentahydrate, %

	Boric acid		Borax		Borax pentahydrate

and sodium perborate for cleaning and bleaching of laundry products; and 2 % as corrosion inhibitors in aqueous systems, especially automotive antifreeze.

In Western Europe about one-half of the B_2O_3 is used in the manufacture of glass-related products. Sodium perborate accounts for about one-third of the total boron consumption as a bleach in high-temperature laundry products.

In Japan 70 % of B_2O_3 consumption is used in glass-related products.

Other minor uses of boric acid and metal borates are listed below.

Boric acid
- Flux in welding and brazing
- Bacteriostat and fungicide
- NF grade as a mild, nonirritating antiseptic
- Cockroach control
- Protection of wood products against insect damage
- Use in nuclear reactor cooling water
- Manufacture of refractories and abrasives
- Catalysts for air oxidation of hydrocarbons

Sodium borates, Calcium borates
- Manufacture of refractories and abrasives
- Metallurgical flux (smelting)
- Neutron absorber in nuclear reactors

Sodium metaborate
- Photographic chemical
- Herbicides
- Detergents and cleansers
- Textile-finishing compounds
- Adhesives

Potassium borates
- Non-sodium alkaline borate source
- Lubricant component
- Solvent for casein
- Welding and brazing flux for stainless steels and various nonferrous metals

Ammonium tetraborate
- Non-alkaline metal borate source

Ammonium pentaborate
- Component in electrolytes for electrolytic capacitors
- Flameproofing formulations
- Paper coating

Lithium meta- and tetraborates
- Glass-making

Barium borates
- Fire retardants
- Mildew inhibitor in latex, paints, plastics, textile, and paper products
- Preservative in protein-based glues

Copper metaborate
- Rot and mildew inhibitor
- Fungicide in lumber and other cellulosic materials
- Oil pigment

Manganese borate
- Printing ink drier

10. Economic Aspects

The estimated world reserves of borate minerals and world production of boron products for 1980 through 1982 are listed in Table 7. Of the total world borates the United States produces

62 %, Turkey 29 %, and all other sources 9 %, based on B_2O_3. World borate consumption in the United States is 30 %, Western Europe 37 %, Japan 5 %, and all other countries 28 %. The European and Japanese borate requirements are served through imports largely from the United States and Turkey. Almost all B_2O_3 production in Turkey and about one-half the production in the United States is exported.

Table 7. Estimated world borate reserves and mine production (as B_2O_3)

Country	Reserves, kt	Production, kt		
		1980	1981	1982
United States	70000	710	670	550
Turkey	70000	339	320	320
South America	35000	–	–	–
Argentina	–	–	30	27
Chile	–	–	1	4
Peru	–	–	3	3
Soviet Union	65000	–	40	40
China	30000	–	5	5
World total	270000	1049	1069	949

Nearly 99 % of the sales volume of borate products consists of borax pentahydrate, borax decahydrate, boric acid, boric oxide, anhydrous borax, colemanite, and ulexite. Borax pentahydrate is the highest volume commercial borate. Until mid-1984, U.S. Borax exported a crude borax pentahydrate, trade name Rasorite-46, containing less than 1 % clay. This product is now exported without clay as borax pentahydrate. Prices of the primary borate products are shown in Table 8.

Table 8. Borate prices [62]

Product	$/t
Borax, decahydrate, technical, granular, 99.5 %, bulk carlots	193 *
Borax, pentahydrate, technical, granular, 99.5 %, bulk carlots	222 *
Borax, anhydrous, technical, 99 %, bulk carlots	622 *
Boric acid, technical, granular, 99.9 %, bulk carlots	609 *
Tincal	148 – 185 **
Ulexite	120 – 170 **
Colemanite, glass quality	255 – 325 **
Colemanite, refining grade	160 – 190 **

* FOB (free on board) rail cars in California, United States.
** FOB ship Bandirma, Turkey

There has been a significant decline in production of anhydrous products because of the rapid increase in fuel costs. In addition there is a trend to use colemanite for the manufacture of textile fiberglass.

11. Toxicology and Occupational Health

Boron is present in animal tissue at about 1 ppm, but has no known essential biochemical function [63]. Humans absorb about 10 – 20 mg of boron in a normal daily diet, mainly from fruits and vegetables. Inhalation of boric acid and borate dust causes only irritation without permanent injury. It is not absorbed when contacted with healthy skin, but can be toxic when used on large areas of burned or abraded skin. The handling of boric acid and sodium borates is not generally considered hazardous [66].

Boric acid has an acute oral LD_{50} (rats) of 4 g/kg; for borax the oral LD_{50} (rats) is 6 g/kg. The TLV and MAK data are given in Table 9 [64], [65].

Table 9. Maximum concentrations in the work environment

Substance	TWA, mg/m^3	STEL, mg/m^3	MAK, mg/m^3
Sodium tetraborates [*1303-96-4*]			
Anhydrous	1	–	–
Decahydrate	5	–	–
Pentahydrate	1	–	–
Boron oxide [*1303-86-2*]	10	20	15

Boron is an essential trace element in higher plant nutrition [67]. At high levels boron becomes toxic, with damage manifested in deformation of leaves, which curl at the edge, often accompanied by necrosis. Fertilizers with calcium tend to reduce this damage [31].

1. Boron

The nonmetallic element boron [*7440-42-8*] is situated in the top position of the third main group in the periodic table. Boron is not found free in nature but is always bound to oxygen. It occurs as orthoboric acid and as alkali-metal and alkaline earth metal borates. The most important sources of boron are the minerals rasorite and kernite, which are found in extensive deposits in California in the Mojave desert. There are also large ore deposits in Turkey and the USSR. Although widespread in nature, boron constitutes only about 3 ppm of the earth's crust [9].

Boron was discovered concurrently by the French chemist GAY-LUSSAC and the English chemist SIR HUMPHRY DAVY in 1808. HENRI MOISSAN [10] first obtained considerable quantities of boron (of 86 % purity) by reduction of boric oxide with magnesium in 1895. The Moissan process is still the basis for commercial production of amorphous low-purity boron.

In 1909 WEINTRAUB [11] succeeded in preparing 99 % pure boron by decomposition of BCl_3 in an electric arc. Since then numerous methods have been developed (see Section 1.4), but still research continues to find methods for producing commercial quantities of pure boron.

1.1. Structure and Polymorphism

There are several allotropic forms of boron. Well established are amorphous boron, α-rhombohedral boron, and β-rhombohedral boron. In addition, four tetragonal forms have been described. However, these are probably stabilized by small amounts of nitrogen or carbon [4].

The β-rhombohedral form is the thermodynamically stable modification at all temperatures. Amorphous boron slowly converts to the β-rhombohedral form at $\approx 1200\,^{\circ}C$ and to α-rhombohedral boron above $1500\,^{\circ}C$. Any type of boron recrystallizes in β-rhombohedral structure when heated above the melting point and cooled.

The unit cell of β-rhombohedral boron contains 105 boron atoms grouped $84\,B + 2\times 10\,B + 1\,B$ in a complex arrangement. The structure of α-rhombohedral boron can be described as a slightly deformed cubic close packing of B_{12} icosahedra. The unit cell contains 12 B atoms at the vertices of the icosahedron.

Amorphous boron exhibits broad reflections in the x-ray diffraction pattern. It is believed to be a frozen-in intermediate between the α- and β-modifications or a microcrystalline deposit of β-rhombohedral boron [4]. Amorphization can be achieved by intensive milling of β-

10.1002/14356007.a04_281

rhombohedral samples [12]. Structures of the other polymorphs are too complex to be described in a few words; however, all boron structures have been discussed thoroughly elsewhere [4].

1.2. Physical Properties

Determination of precise physical properties of boron is made more complicated by the structural polymorphism and purification problems. Some values, rather arbitrarily collected from the literature, are listed below.

Atomic number	5	
Relative atomic mass	10.811	
Melting point	$2050 \pm 50\,^{\circ}C$	
Sublimation point	$2550\,^{\circ}C$	
Density ($20\,^{\circ}C$)	$2.3\,g/cm^3$	amorphous
	2.35	β-rhombohedral
	2.46	α-rhombohedral
	2.99	liquid at *mp*
	2.13	solid at *mp*
Crystal structure	amorphous, α-rhombohedral, β-rhombohedral, four tetragonal	
Hardness (Knoop)	$2390\,kg/mm^2$	crystallized from melt
	2690	vapor deposited
Electrical resistivity (300 K)	$7.5 \times 10^2\,\Omega\,cm$	amorphous
	7×10^5	β-rhomb., single crystal
	$10^6 - 10^7$	β-rhomb., polycrystalline
Heat capacity C_p	$12.054\,J\,K^{-1}\,mol^{-1}$	amorphous at 300 K
	11.166	β-rhomb. 300 K
	33.955	solid at *mp*
	39.063	liquid at *mp*
Entropy S (298 K)	$6.548\,J\,K^{-1}\,mol^{-1}$	amorphous
	5.875	β-rhomb.
Enthalpy of fusion ΔH_f	50.2 kJ/mol	
Enthalpy of sublimation ΔH_s	572.7 kJ/mol	

Boron is the second hardest element, the diamond allotrope of carbon being the hardest. α-Rhombohedral boron is red to brown; β-rhombohedral boron lustrous gray black; and amorphous material is brown to gray. The electrical resistivity changes drastically with temperature, varying from $10^{11}\,\Omega\,cm$ at $-160\,^{\circ}C$ to $10^6\,\Omega\,cm$ at $20\,^{\circ}C$ and to $0.1\,\Omega\,cm$ at $700\,^{\circ}C$ [4] for polycrystalline β-rhombohedral boron, be havior characteristic of a semiconductor. Detailed information about optical, magnetic, electrical, thermodynamic, and other properties of the various boron polymorphs are given in the literature [4], [5].

Boron is composed of two stable isotopes, ^{10}B [*14798-12-0*] and ^{11}B [*14798-13-1*]. Their nuclear properties are summarized in Table 1. The nuclear spin permits NMR spectroscopy. The high value of thermal neutron cross section of the isotope ^{10}B makes boron useful as a neutron absorber in nuclear power plants.

Table 1. Nuclear properties of boron

Property	Nuclide	
	^{10}B	^{11}B
Relative atomic mass	10.0129	11.0093
Natural abundance, %	19.8	80.2
Nuclear spin	+3	−3/2
Magnetic moment, nuclear magnetons*	+1.80063	+2.68857
Quadrupole moment, barn**	+0.074	+0.036
Cross section for (n, α), barn**	3837	0.005

* 1 nuclear magneton $= 5.0508 \times 10^{-27}\,A\,m^2$.
** 1 barn $= 10^{-28}\,m^2$.

1.3. Chemical Properties

The chemical properties of boron are determined to a large extent by its small atomic radius (0.25 nm) and high ionization potentials.

Ionization energy		
$B \longrightarrow B^+$	798 kJ/mol	(8.27 eV)
$B^+ \longrightarrow B^{2+}$	2426	(25.15)
$B^{2+} \longrightarrow B^{3+}$	3658	(37.92)
Standard electrode potential		
$B + 3\,H_2 \rightleftharpoons OH_3BO_3 + 3\,H^+ + 3\,e^-$	−0.73 V	
Electron affinity	32 kJ/mol (0.332 eV)	
Electronegativity	2.04 (Pauling)	
	2.01 (Mulliken)	
Ionic radius	0.25 nm	
Atomic radius	0.80 – 0.95 nm (depending on type of bonding)	
Standard enthalpy of formation		
BF_3	−1136 kJ/mol	
BCl_3	−402	
BBr_3	−239	
B_2O_3	−1269	
BN	−256	

The electronic configuration $2s^2 2p^1$ dictates predominant trivalency. However, simple B^{3+} ions do not exist.

Because boron has more orbitals available for bonding than electrons (4 orbitals, 3 electrons), it is an electron-pair acceptor, a Lewis acid, and it has a tendency to form multi-center bonds. Other dominant characteristics are the high affinity for oxygen and the tendency to combine with most metals to give refractory alloy-like metal borides.

The chemical behavior of elemental boron depends upon the morphology and particle size. Generally speaking, crystalline boron is rather unreactive, whereas amorphous boron does react more readily. At room temperature all modifications of boron are relatively resistant to chemical attack.

No direct reaction occurs with hydrogen, but indirect synthesis leads to a variety of boron hydrides (→ Boron Compounds).

The halogens react to form the trihalides:

$$2\,B + 3\,X_2 \longrightarrow 2\,BX_3$$

Fluorine reacts spontaneously at room temperature; chlorine, at 500 °C; and bromine, at 600 °C [13].

Reaction with oxygen starts at ≈ 600 °C but is restrained by the formation of a glassy liquid B_2O_3 film on the boron particles [14]. Boron reacts with sulfur to form glassy B_2S_3 and with Se to form B_2Se_3, both at ≈ 600 °C. There is no reaction with Te. With nitrogen, boron nitride, BN, is formed at 1100 °C. Phosphorus reacts completely at 1000 °C to give BP. Arsenic forms BAs at 800 °C under pressure.

Boron and carbon react to give $B_{12}C_3$ above 2000 °C; with silicon, B_4Si and B_6Si are formed. Heterocyclic compounds containing C, N, S, O, and boron have interesting structures and properties (see Carboranes, Borazine, Borthiine, and Boroxine under → Boron Compounds). There is also a large variety of organoboron compounds [15].

When it does react, elemental boron is an effective reducing agent. Water vapor is reduced at 800 °C to give H_2 and B_2O_3. Carbon monoxide is reduced at 1200 °C; boron burns in carbon dioxide at red heat. Nitrogen oxides are reduced to give BN and B_2O_3. Sulfur dioxide is also reduced. When transition metal oxides like Fe_2O_3, TiO_2, and Cr_2O_3 are reacted with elemental boron, B_2O_3 and metal borides form. Up to 1400 °C alkaline-earth oxides and aluminum oxide do not react with boron.

Boron is not attacked by aqueous NaOH but reacts completely with molten Na_2CO_3 or molten mixtures of sodium carbonate and sodium nitrate.

Boiling nonoxidizing acids, such as HF, HCl, HBr, or dilute sulfuric or phosphoric acid, do not attack boron. However, vigorous reaction occurs with concentrated HNO_3 or with HNO_3– H_2O_2 mixtures.

The chemical properties of boron are summarized in [17].

1.4. Production

A variety of preparative methods have been described. The following are the most important methods [6]:

1) Reduction of boric oxide with magnesium
2) Reduction of boron halides or fluoroborates with sodium or another metal
3) Reduction of boron halides with hydrogen
4) Thermal decomposition of boron compounds, especially boron halides and hydrides
5) Electrolysis of molten borates or fluoroborates

The modification of boron formed depends primarily on temperature and reaction time, only secondarily on the method [18]. As a rule of thumb, temperature below 900 °C and short reaction time produce amorphous boron; temperature above 1400 °C and long reaction time produce β-rhombohedral or the tetragonal modifications. The optimum conditions for formation of α-rhombohedral boron are in between.

The usual method for commercial production of large quantities of amorphous boron is the *reduction of boron trioxide with magnesium* in a thermite-like reaction [19–21]. The principles of this method date back to the work of Henri Moissan [10].

$$B_2O_3 + 3\,Mg \longrightarrow 2\,B + 3\,MgO$$

Simultaneously MgO reacts with excess B_2O_3:

$$MgO + B_2O_3 \longrightarrow Mg(BO_2)_2$$
$$MgO + 2\,B_2O_3 \longrightarrow MgB_4O_7$$

The reduction is very quick and highly exothermic; finely divided material may react explosively [7].

Reaction is smoother if there is an excess of B_2O_3 [7], [22]:

$$2\,B_2O_3 + 3\,Mg \longrightarrow 2\,B + Mg_3(BO_3)_2$$
$$4\,B_2O_3 + 3\,Mg \longrightarrow 2\,B + 3\,Mg(BO_2)_2$$

The optimum ratio B_2O_3 : Mg is about 1.8 : 3 [7]. Reaction is carried out in vertical steel retorts shielded from oxygen by a flow of argon. It is initiated by electric spark and igniter mixture or by external heating.

After cooling, the reaction mass is crushed to 1-mm particles and leached twice with hydrochloric acid. Crude amorphous boron of 86 – 88 % purity is obtained [21]. This material can be upgraded by treatment with B_2O_3 [22] or KHF_2 and KBF_4 [23], [24], subsequent leaching with acid, and final heating in a vacuum to remove boron suboxide and metals [25]. The boron content is then 90 – 92 or 95 – 97 %, adequate for use in pyrotechnics and fluxes.

Reduction of KBF_4 by sodium

$$KBF_4 + 3\,Na \longrightarrow 3\,NaF + KF + B$$

was used for the commercial production of boron in Germany until the end of the 1950s [26].

A common problem of metallothermic reduction is incomplete reaction and formation of nonremovable metal borides.

Samples of very pure boron, > 99 % B, can be obtained by *reduction of boron halides with hydrogen*, especially BBr_3 [27], [28] and BCl_3 [29–32]. This is also the method of choice for laboratory synthesis [27], [29]. The halides can be purified by distillation prior to reduction [4], [27]. However, the efficiency of the hydrogen reduction process is rather low [19], yields of 5 – 25 % being the usual. Unreacted boron halide must be recycled [30], washed out, or removed by other methods [33]. This complicates the process and makes it expensive.

Very pure boron is also obtained by *thermal decomposition* of BI_3 [34], [35], BBr_3 [36], or boron hydrides [37], [38] on tungsten wires or another type of incandescent filament. Boron of 99.9999 % (six nines) purity was obtained by decomposition of diborane and subsequent zone melting [39].

Electrolysis of molten borates or KBF_4 [40] is not an important method for commercial or laboratory preparation although it has been mentioned in numerous articles.

Boron can be refined either by zone melting [6], [35], [39], [41], [42] or volatilization of impurities in high vacuum or hydrogen at 2000°C [25], [35].

1.5. Chemical Analysis, Storage, Safety

Analysis. Boron content in elemental boron is generally *determined quantitatively* by decomposition to borate with fused carbonate in a platinum crucible, subsequent acid leaching, neutralization, addition of mannitol, and titration of boric acid. The mixture HNO_3–H_2O_2 also decomposes boron samples. Metal impurities in boron, such as Mg, Na, and Fe, are determined by atomic absorption or emission spectrometry after decomposition of the sample [43]. Chlorine and fluorine are determined by titration [44]. The elements O, N, H, P, Si, and C are difficult to determine. However, vacuum hot extraction and combustion methods [42], [43] or spark source mass spectrography [35], [45] can be used.

A sensitive *qualitative* test for boron is the green flame test. The sample is usually decomposed to methyl borate by heating a mixture of the sample, sulfuric acid, and methanol to ignition.

Storage. Dry boron is not very sensitive to oxidation. It is *packaged* in airtight metal drums, cardboard or plywood containers, or glass bottles [46]. Boron powder, like other combustible material, presents a dust explosion hazard. The lower explosive limit was determined to be 125 g/m^3 in air [47].

Boron ignites in air at 600 – 800 °C but does not burn violently because of the formation of a glassy boric oxide film that prevents the material from oxidizing rapidly [14]. Burning boron should be covered with sand, aluminum oxide, sodium chloride, or the like. Water must not be used, because of the formation of inflammable hydrogen. Boron is an explosion hazard when

mixed with strong oxidizing agents, such as nitrites, chlorates, lead dioxide, and silver fluoride. Such mixtures can react violently and even explode [13], [14], [16].

Safety. Elemental boron is considered to be nontoxic because of its chemical inertness and insolubility. In contrast, most boron compounds, especially the hydrides, are extremely toxic [48] (see Toxicology under → Boron Compounds). During the production process leading to boron the possible formation of any toxic boron hydrides must be either avoided or controlled.

1.6. Uses, Economic Aspects

Relatively large quantities of amorphous boron (90 and 95 % B) are used as additives in pyrotechnic mixtures, especially in flares, igniters, and delay compositions (→ Pyrotechnics); solid rocket propellant fuels [49]; and explosives [50]. Some boron is needed for the preparation of refractory metal boride additives for cemented carbides. Boron is also a useful reducing additive in fluxes for soldering stainless steel.

Use of boron in electronics is limited to high-purity boron (> 99.99 %). It is used as a ppm additive for germanium and silicon to make *p*-type semiconductors [51]. Crystalline high-purity boron is used in thermistors [52], [53] and delay lines [54]. Boron filaments have been developed as reinforcing material for light-weight, stiff composites for use in commercial and military aircraft [55]. Epoxy resins [56], polyamides, aluminum, magnesium, and other materials are the matrix [57], [58]. However, graphite filaments have replaced boron filaments in many applications.

In nuclear technology thin films of boron are used in neutron counters [52]. Boron powder dispersed in polyethylene castings is used for shielding against thermal neutrons [59]. In addition, composites of boron with Al or Fe, especially when enriched in ^{10}B, are used as neutron shields and absorbers in nuclear reactors [59].

Boron is an effective deoxidizing agent, e.g., for production of pure copper [60]. It also is important in the preparation of amorphous magnetic metals and alloys [61]. Boron, as ferroboron, is used in microalloyed steel (0.001 % B). This steel exhibits excellent resistance to stress cracks as well as improved tensile strength and hardness.

Amorphous boron of 90 – 92 % purity costs about DM 250 – 300 (≈ $ 100) per kg (1984). Material of higher purity is much higher in price: very pure boron (> 99.99 %, four nines) may cost up to DM 10000 (≈ $ 3500) per kg and more. Boron enriched in ^{10}B costs $ 9 – 10 per gram [59].

The leading *producers* are H. C. Stark, Goslar, Federal Republic of Germany, and Kerr McGee Chemical Corp., Oklahoma, United States. There are further production facilities at Degussa AG, Frankfurt am Main; Elektroschmelzwerk Kempten, München; Union Carbide Chemical Corp., New York; NL Industrial Corp., Wilmington, Delaware, United States; Murex Ltd., Rainham, United Kingdom; and Kawecki-Billiton Corp., Arnhem, the Netherlands [62]. Boron is also produced in the Soviet Union.

Total production is estimated to be 30 –50 t/a.

2. Ferroboron and Other Boron Master Alloys

Ferroboron is basically an iron – boron alloy containing 10 – 20 wt% B. It is used mainly in the steel industry. Ferroboron was first produced in 1893, by Henri Moissan [63], from boric acid, iron, and carbon in a single-phase electric-arc furnace lined with carbon. Ferroboron produced in this way contains carbon. The introduction of the thermite reaction by Goldschmidt in 1898 led to the aluminothermic reduction of boric oxide to ferroboron, for years the main commercial method for producing ferroboron. The carbothermic process has again found use for the production of ferroboron, now as a raw material for the manufacture of amorphous metals (→ Metallic Glasses). Aluminothermic ferroboron contains residual aluminum, which causes severe casting problems.

2.1. Physical Properties

In the system iron – boron, shown in Figure 1 [64], there are two intermetallic compounds, FeB [*12006-84-7*] and Fe_2B [*12006-86-9*] (ϱ

6.3 and 7.3 g/cm^3, respectively). The crystal structure of FeB is orthorombic ($a = 0.5502$, $b = 0.2948$, $c = 0.4057$ nm), whereas that of Fe_2B is tetragonal ($a = 0.5109$, $c = 0.4249$ nm). Additional physical properties of the two iron borides are summarized in Table 2. Also see [68].

Figure 1. Phase diagram iron – boron [64]

Table 2. Properties of Fe_2B and FeB [65–67]

Property	Fe_2B	FeB
Microhardness, Vickers, 100 g, kN/mm^2	13.24	16.19
Thermal conductivity, W cm^{-1}K^{-1}	0.2 – 0.3	0.1 – 0.2
Electrical resistivity, at room temperature, μΩ cm	≈ 10	≈ 20
Temperature coefficient of resistance, μΩ/K	0.18	0.4
Curie temperature, K	1015	598
Coefficient of linear expansion (300 – 1000 K), K^{-1}	8×10^{-6}	10 – 16×10^{-6}

The enthalpies of formation at 1385 K have been determined by high-temperature solution calorimetry [69]: -67.87 ± 8.05 kJ/mol for Fe_2B and -64.63 ± 4.34 kJ/mol for FeB.

Commercial ferroboron alloys, either aluminothermic or carbothermic, are bright silver and brittle with a fine or coarse crystalline fracture. The density depends mainly on the boron content:

boron, wt %	20.2	17.9
aluminum, wt %	2.7	0.8
density, g/cm^3	6.02	6.41

2.2. Chemical Properties

Commercial ferroboron changes in appearance over prolonged exposure to humid air; its bright silver disappears, the surface turning dull gray, with almost red "rusty" stains. Ferroboron dissolves in mineral acids (Section 2.7). Distilled hot water may react slightly with ferroboron [70]. Some contradictory statements about the chemical behavior of ferroboron in the literature are probably due to other elements in the alloy. Fe_2B dissolves in HCl (1 : 2), hydrogen and boranes evolving, the latter hydrolyzing into suboxides [71], [72]. FeB is resistant to HCl ($\varrho = 1.19$ g/cm^3) and H_2SO_4 ($\varrho = 1.84$ g/cm^3), both at room temperature and at their boiling point. FeB dissolves completely in HNO_3. Both FeB and Fe_2B react with nitrogen at temperatures above 350 °C to give boron nitride [65].

The behavior of boronized steels, i.e., steel with thin layers of FeB on the surfaces, was discussed by A. Matuschka [66]. Such steels are oxidation resistant up to 700 – 900 °C. The boronized steel CK45 (AISI 1042) is resistant to 20 % HCl, 10 % H_3PO_4, and 10 % H_2SO_4 at 56 °C. Stainless steels, such as X10CrNiTi 18 9 (Werkstoff Nr. 1.4541, AISI 321, SAE 30321) can be made more resistant to attack by 20 % HCl or 10 % H_2SO_4 at 56 °C by boronizing the surface.

2.3. Raw Materials

The following boron minerals can be used for the manufacture of ferroboron: colemanite (51 % B_2O_3), pandermite (48 % B_2O_3), priceite (51 % B_2O_3), and boracite (62 % B_2O_3). However, the raw materials most commonly used are boric oxide (≈ 99 % B_2O_3) and boric acid (≈ 57 % B_2O_3).

2.4. Production

Boric oxide can be reduced by carbon, aluminum, or magnesium. Reduction by silicon is incomplete. Figure 2 shows the calculated free energies of the corresponding reactions as a function of temperature [67]. For commercial production, either reduction by carbon (carbothermic or endothermic) or reduction by aluminum, sometimes with some magnesium (aluminothermic or exothermic) is usual. The coreduction of iron and boric oxide proceeds more readily than the reduction of either alone because of the formation of the borides Fe_2B and FeB. Iron can be replaced by other boride-forming metals, manganese, nickel, or cobalt. In carbothermic reduction there is a tendency to form boron carbide, thus leading to a carbon-containing ferroboron.

Figure 2. Free energies ΔG^0 of reactions reducing boric oxide as a function of temperature
I $2/3\,B_2O_3 + 2\,C \longrightarrow 4/3\,B + 2\,CO$
II $2/3\,B_2O_3 + 7/3\,C \longrightarrow 1/3\,B_4C + 2\,CO$
III $2/3\,B_2O_3 + 4/3\,Fe + 2\,C \longrightarrow 4/3\,FeB + 2\,CO$
IV $2/3\,B_2O_3 + Si \longrightarrow 4/3\,B + SiO_2$
V $2/3\,B_2O_3 + 4/3\,Al \longrightarrow 4/3\,B + 2/3\,Al_2O_3$
VI $2/3\,B_2O_3 + 2\,Mg \longrightarrow 4/3\,B + 2\,MgO$

Aluminum and boron also form borides (see Metal Borides under → Boron Carbide, Boron Nitride, and Metal Borides), and this results in residual aluminum in aluminothermic ferroboron.

2.4.1. Carbothermic Production

In order to produce a carbothermic ferroboron with a low carbon content the boron content must be high, i.e., the higher the boron content the lower the carbon solubility and thus carbon pick-up.

The reduction of boric oxide by carbon requires high temperature; therefore, the process is carried out in an electric-arc furnace (single- or three-phase type) of capacities up to 1500 kV A. These are relatively small production units, for the worldwide demand for ferroboron is low compared with that for other electrothermic ferro alloys.

The London & Scandinavian Metallurgical Co., United Kingdom, produces a ferroboron with 16 – 18 % B, 0.5 % C, and < 0.15 % Al by carbothermic reduction of boric oxide.

In a Japanese patent [73] the carbothermic production of ferroboron from boric acid, iron powder, and charcoal in a Héroult-type electric-arc furnace with carbon lining is claimed. One example describes the production of an alloy with 10.3 % B, 2 % Si, and 0.98 % C in a 350-kW three-phase electric-arc furnace. The mix is 100 parts boric acid, 135.8 parts iron powder (92.9 % Fe), and 57 parts charcoal powder. The boron recovery is 81.7 %, and the power consumption 4550 kWh per tonne of alloy. Another example describes the small-scale production of an alloy containing 15.3 % B. Another Japanese patent [74] claims the carbothermic production of a B- and Si-containing alloy, e.g., 3.3 wt% B, 2.9 wt% Si, and 3.0 wt% C, in a special vertical blast furnace. The ferroboron is intended for use in the manufacture of amorphous alloys.

The production of ferroboron from pig iron swarf and boric acid in an electric-arc furnace with a final oxygen blow leads to an alloy with 16.3 % B, 0.03 – 0.06 % Al, and 0.03 – 0.06 % C. The boron recovery in small-scale runs is said to be 60 – 65 %; the power consumption, ≈ 16500 kWh per tonne of alloy [75]. Silicon-containing boron alloy can be produced by carbothermic reduction. The process is described by K. D. Frank in [76]. A mixture of 100 parts colemanite, 100 parts quartzite, 40 parts iron turnings, and 60 parts low-temperature coke is charged to a 1000-kW electric-arc furnace. A metal containing 5.35 % B, 37.2 % Si, and 0.21 % C is tapped. Boron recovery is 70 %, and the power consumption is 6000 kWh per tonne of alloy.

Gesellschaft fuer Elektrometallurgie mbH, Duesseldorf, Federal Republic of Germany, has

developed a process for the carbothermic production of ferroboron containing 15 – 20 % B and < 0.1 % Al in a three-phase submerged arc furnace, whereby boric oxide and iron oxide are simultaneously reduced by charcoal and other low-density carbonaceous materials, e.g., wood chips [77]. Nickel boron can also be produced carbothermically. Boric oxide and/or boric acid and nickel are the raw materials. London and Scandinavian Metallurgical Co., London, United Kingdom, produces a nickel boron containing 15 – 18 % B; 0.5 and 0.15 % C (max.); and 0.20 % Al (max.) in the electric-arc furnace by carbon reduction.

2.4.2. Aluminothermic Production

Ferroboron can be made batchwise in a convenient way by the reduction of boric oxide and iron oxide with aluminum powder. Some magnesium in the aluminothermic mix is beneficial: Magnesium is the stronger reducing agent at temperatures below its boiling point, whereas aluminum is more effective above the boiling point of magnesium, where such metallothermic reactions generally take place.

The aluminothermic coreduction of boric oxide and iron oxide (Fe_2O_3) is highly exothermic, and only a little additional energy is necessary for a self-propagating reaction (→ Aluminothermic Processes). The thoroughly mixed compounds are charged into a refractory-lined pot and ignited, either the whole mix (top firing) or by igniting a starting mix, the rest then charged as the reaction proceeds over a few minutes. The liquid metal and slag separate on account of differing densities, and after cooling the metal button, up to 1500 kg, is removed. After mechanical cleaning, the metal button is broken and crushed to the desired size. The companies of the Metallurg Group [78], who produce ferroboron from boric oxide, iron oxide, and aluminum powder, obtain boron recoveries of 70 – 75 % for the 18 – 20 % B grade and 80 – 85 % for the 15 – 18 % B grade by optimizing process parameters. The aluminum consumption can be as low as 4.8 – 5 kg Al per kg of B.

N. A. Chirkov et al. [79] investigated heat balances for an electro-aluminothermic ferroboron process using either 1) boric oxide or 2) boric acid as the raw material. Three different mixes – igniting, main, and precipitation – are charged consecutively into a three-phase electric-arc furnace and reacted to produce a ferroboron melt with ≈ 20 % B. The composition of the charges and the results are summarized in Table 3. The heat balances for these two cases are shown in Table 4. The investigators are convinced that the process can be optimized to improve the boron recovery and the consumption figures.

When borate ores such as boracite or colemanite are used as raw materials, instead of boric oxide, the aluminothermic process gives boron recoveries as low as 40 – 50 % [80–82]. The specific aluminum consumption is normally higher because the process needs additional energy, in form of either a booster (peroxides or chlorates plus aluminum powder) or in the form of electricity by smelting the mix in the electric-arc furnace (electro-aluminothermic process).

Complex boron additives for steel, which contain boron in a dilute alloy together with protective elements, are produced from ferroboron and other alloying elements by a melting process (see Section 2.5, Table 7, and [83]). Other boron master alloys such as nickel boron and cobalt boron with ≈ 15 % B and 0.1 % or 1.0 % Al (max.) can be produced aluminothermically using boric oxide and nickel or cobalt (as metal and/or oxide) [84]. Copper boron with ca. 2 % B is commercially produced by Gesellschaft fuer Elektrometallurgie [85], using an electromagnesiothermic process with copper and boric oxide as raw materials. Aluminum master alloys with 2.5 – 4.5 % B and ≈ 5 % Ti + 1 % B are produced in an induction furnace by adding potassium boron fluoride and potassium titanium fluoride to an aluminum bath [86].

2.5. Quality Specifications for Commercial Grades

Quality standards are specified in Germany by DIN 17567 [87], which also describes sizing, sampling, analytical methods, shipment, and storage. Analyses of the standard grades are summarized in Table 5. The American ASTM recognizes six grades of ferroboron; analyses are given in Table 6. Ferroboron is shipped in various sizes. In Europe pieces of fist size and

C 2	19.0	24.0	1.5	4.0	8.0

in the United States sizes such as 2 in or 1 in x Down are commercial. Ferroboron can also be ground to powder of desired size (e.g., 20 mesh x D, i.e., less than 0.84 mm). In the United States, where the use of boron in steel is fast growing, and also in the United Kingdom, special boron alloys have been developed as hardenability intensifiers (Table 7). These complex alloys contain elements to protect boron against oxidation (Al, Si) and boron nitride formation (Ti, Zr) [89]. Boron-containing aluminum master alloys (Table 8) are standardized in Germany [90]. Nickel boron, cobalt boron, and copper boron are not standardized. Typical analyses for commercial alloys are given in Table 8.

In the United States and the United Kingdom special boron additives for the steel industry have been developed. The *trade names*, e.g., BATS (abbreviation for boron-aluminum-titanium-silicon), are shown in Table 7.

2.6. Storage and Shipment

Ferroboron and other boron master alloys are generally not toxic, and there is no special legislation on use and handling. Ferroboron is gener-

ally packed in steel drums marked with material grade, size, lot number, and producer. The shipment is accompanied by a data sheet on safe handling including physical and chemical properties, safe storage, and handling directions, e.g., use of protective gloves or dust respirators. Ferroboron and other boron master alloys and additives should be stored in a dry area in their original containers.

2.7. Chemical Analysis

For the determination of boron in ferroboron the sample is dissolved in HCl (1 : 1) or H_2SO_4 (1 : 1) containing a few drops of HNO_3 and refluxed. Residues rich in boron are fused with sodium peroxide. The solution is passed through an ion-exchange column, neutralized, diluted with polyalcohol, and titrated with sodium hydroxide [91–93]. Small amounts of boron in steel are determined by special methods [89]. One photometric determination of boron in steel is the curcumin method. A fully automated determination of boron in ferroboron, aluminum, and complex ferro alloys by neutron transmission is a convenient method for routine analyses [94]. Standard analytical methods in the United States and the United Kingdom [95], [96] have been described.

2.8. Pollution Control

During production the usual proscriptions on pollution have to be obeyed.

In both the carbothermic and the exothermic reduction processes the dust off-gases have to be cleaned, either dry in bag filters or electrostatic dust precipitators or wet in disintegrators or Venturi scrubbers (O. Renz in [76]). A special combined dry – wet cleaning plant for the off-gases of an aluminothermic plant is described by Seybold [97].

2.9. Uses

The main use of ferroboron is in steel (→ Steel) [89], [98]. Very small amounts of boron improve the hardenability of both plain carbon and alloyed steels. Boron acts as a hardenability intensifier of other hardening elements, such as carbon, manganese, chromium, molybdenum, etc. The boron should be present in the concentration range of 5 – 15 ppm (max., 30 ppm). Thus the use of boron saves the expense of more costly alloying elements. Because of the high affinity of boron for oxygen and nitrogen, also that dissolved in steel, boron has to be protected from these two elements. Therefore, good predeoxidation by calcium, aluminum, or silicon and denitrification by titanium or zirconium are necessary. In the United States and the United Kingdom complex boron master alloys that contain these protective elements have been developed and have proved very effective for controlled boron addition to steels. In case-hardened steels, boron exhibits better hardenability and strength; in nonaging steels, especially for the automotive industry, the sheet-forming properties are improved. Boron also offers benefits in high-strength low-alloy (HSLA) steels, and it improves the cutting properties in high-speed steels.

In stainless steels of the chrome – nickel type (ASTM 316), 0.004 – 0.009 % B significantly improves the ductility in the hot forming range (950 – 1250 °C). In very low concentration (0.002 – 0.005 %) boron is beneficial to creep properties in austenitic heat-resistant stainless steels, as well as in ferritic steels, then in combination with titanium, molybdenum, or niobium. Steels with boron contents up to 2.5 % are used for control rods in nuclear reactors because the thermal neutron cross section of boron is so high. Boron is also used in hardfacing and abrasion-resistant alloys; e.g., Colmonoy, a Ni-Cr-Si-B alloy containing up to 3 % B, and Stellite, an abrasion-resistant Co-Cr-W alloy containing up to 2.5 % B.

The copper – boron master alloy is the best agent for deoxidizing copper for the production of a highly conducting metal. Aluminum is treated with aluminum – boron master alloy to increase the electrical conductivity and with aluminum – titanium – boron master alloy to refine the grain [86].

A new field of boron usage is the production of amorphous alloys or metallic glasses (→ Metallic Glasses). Intensive development has been carried out by Allied Chemical Corp.

[99]. These alloys consist of a transition metal (Fe, Ni, or Co) and about 20 mol % of a metalloid (B, C, Si, or P). They exhibit extraordinary physical properties, especially the magnetic properties, and may be used for low-hysteresis-loss transformer cores [100].

2.10. Economic Aspects

The consumption of ferroboron is relatively low due to the small concentrations necessary in steel. In the Western World and Japan, ferroboron production was ≈ 1400 t/a in 1982 and ≈ 2000 t/a in 1983, showing an increasing tendency. In 1981 only 2 % of the total boron consumption in the United States was for the metallurgy and nuclear fields [101] (→ Boron Compounds). According to American Metal Market (28 Dec. 83), ferroboron costs $ 3.89 per pound (one pound = 454 g); nickel boron, $ 5.57 per pound of the regular grade, $ 5.67 per pound for the low-aluminum grade, and $ 6.30 per pound for the low-carbon grade.

2.11. Toxicology and Industrial Hygiene

Ferroboron and boron master alloys are generally not toxic, but in the handling of raw materials for their production protective measures must be taken, e.g., the use of protective gloves and glasses as well as dust respirators when handling boric acid. In the production facilities the usual protective measures (clothing, glasses, dust respirators) must also be taken.

1. Boron Carbide

Boron carbide [12069-32-8] belongs to the important group of nonmetallic hard materials, which includes alumina, silicon carbide, and diamond [1]. Although it was first prepared over a century ago, in 1883, by JOLY [2], the formula B_4C was assigned only in 1934 [3]. Today a homogeneity range from $B_{4.3}C$ to $B_{10.4}C$ has been established. The composition of commercial boron carbide is usually close to a boron : carbon stoichiometry of 4 : 1, the stoichiometric limit on the high-carbon side.

Boron carbide is an exceedingly hard material, inferior in hardness only to diamond and cubic boron nitride. In addition, it has a high melting point, high mechanical strength combined with low density, and high neutron cross section, and is a semiconductor. General information about boron carbide is available in the reviews of LIPP [4], THEVENOT et al. [5], [6] and TELLE et al. [7].

1.1. Crystal Structure

Structurally, boron carbide can be considered a prototype of the so-called interstitial compounds of α-rhombohedral boron [8], which include $B_{12}C_3$ [12075-36-4] (= B_4C), $B_{12}C_2Al$ [9], $B_{12}S$, $B_{12}O_2$, $B_{12}As_2$, $B_{12}P_2$, and $B_{3-4}Si$ [10]. The crystal structure for these materials consists of icosahedra that occupy the points of a rhombohedron, plus a chain of atoms that runs along the *c* axis of the rhombohedron. For the most part, boron atoms occupy the points of the icosahedra. The second constituent — C, Al, O — in general occurs on the chain (Fig. 1). (There is no chain at all in α-rhombohedral boron.) The rigid framework of polyatomic units of closely bonded atoms is reflected in the refractory nature and great hardness.

Figure 1. The structure of boron carbide for the stoichiometry $B_{13}C_2$.

For compositions close to $B_{12}C_3$, the lattice parameters are a_H = 0.55980 nm and c_H = 1.20707 nm [11]. However, the details of the boron carbide structure [12], [13] are not firmly established. According to investigations [14] the sequence C–B–C can be assumed for the chain. In addition to these two carbon atoms per unit cell, carbon likely replaces boron at the boron sites in the icosahedra. With 15 atoms per unit cell ($B_{12}C_3$) and 20 mol % C, boron carbide can be reformulated as $(B_{11}C)CBC$ to show this effect. However, SCHWETZ and KARDUCK [15] reported $B_{4.3}C$ as the carbon-rich limit of the homogeneity range of boron carbide. Optical absorption and reflectivity measurements on $B_{4.3}C$ indicated a structure with 81 % C – B – C chains, 19 % C – B – B chains, and exactly one carbon atom located in the $B_{11}C$ icosahedral site [16].

On the boron-rich side the extension of the homogeneity range to 8.7 mol % C, the ratio B : C = 10.4, has been reported by BOUCHACOURT, THEVENOT [17], who propose the structural formula $B_{12-x}C_x(C/B_xC_{1-x}/C)$ and n = 15.33 atoms per unit cell for $B_{10.4}C$. The density of boron carbide at the

boron-rich end is 2.465 g/cm^3; the volume of the unit cell, only 2.5 % larger than B_4C, corresponding to the lattice parameters a_H = 0.5651 nm and c_H = 1.2196 nm.

1.2. The Boron – Carbon System

Although numerous studies are available, not all parts of the B – C system have yet been fully elucidated.

SAMSONOV, SHURAVLOV, et al. [18], [19] reported the compounds $B_{13}C_2$ and $B_{12}C_3$, both with a large homogeneity range, in addition to the carbon-rich BC_2 and the boron-rich $B_{12}C$ phases. In the diagram of DOLLOFF [20], rhombohedral $B_{13}C_2$ and $B_{12}C_3$ phases are combined with a wide range of solid solubility of only one carbide phase, $B_{4+x}C$, which is stable only below 1800 °C. ELLIOT [21] reported the solid solubility of boron carbide from ca. 8 to 20 mol % C over the temperature range from room temperature to the melting point of 2450 °C. The B_4C – C eutectic temperature was reported to be 2375 °C at 29.0 mol % carbon. Investigations by KIEFFER et al. [22] support this broad range of solid solubility. In addition to the compounds given in these publications, $B_{25}C$ [23], B_8C [24], and $B_{13}C_3$ [25] have been reported. These are likely low-temperature phases, which are often observed in chemical vapor deposition. THEVENOT and BOUCHACOURT [5], [17] postulated a peritectic transformation of the β-rhombohedral boron – carbon mixed crystal, giving homogeneity range limits of $B_{10.4}C$ (8.8 mol % C) and $B_{4.0}C$ (20.0 mol % C). Their X-ray diffraction studies indicated a discontinuity in the lattice parameters at the composition $B_{6.5}C$. According to the phase diagram reported in 1983 by BEAUVY [26], the carbon-rich limiting composition corresponds to $B_{3.63}C$, i.e., "$B_{11}C_3$" with 21.6 mol % C. Investigations of the B – C system indicated [15], however, that the carbon content of fused boron carbide in equilibrium with graphite is only 19.2 mol%, corresponding to the formula $B_{4.3}C$. The phase diagram is presented in Figure 2. Recent careful measurements of the lattice constants on high-purity boron carbide showed the boundaries of the single-phase region to be at about 9 atom % C and near to, but likely some what less than, 20 atom % C [11]. Information on phase equilibria in the quaternary system B — C — Si — N is available in [27].

Figure 2. The B – C phase diagram [15]

The degenerated reaction at the B-rich corner is most probably an eutectic.

1.3. Physical Properties

The purest B_4C crystals yet obtained by the electrothermic production process are deep black and shiny, a contrast to SiC crystals, which in their purest form are transparent and colorless. The crystals melt congruently at ≈ 2450 °C; the liquid boils above 3500 °C. The density of B_4C having the natural isotopic composition is 2.52 g/cm^3; $^{10}B_4C$ is less dense, 2.37 g/cm^3.

The Knoop microhardness number HK-0.1, i.e., the hardness measured with a load of 0.1 kp (≅ 0.98 N), is ≈ 3000 [28] (2000 for α-Al_2O_3, 2600 for SiC and elemental boron, 4700 for cubic BN, and 7000 – 8000 for diamond). Therefore, except for diamond, the hardest known materials all contain boron. Table 1 presents some mechanical properties of hot-pressed B_4C and B_4C-based composites manufactured by ESK. The fracture mode of these materials is almost 100 % transgranular [29]. Boron carbide must be considered to be a refractory material, since hardness and strength do not degrade up to 1500 °C in an inert atmosphere [4].

Table 1. Mechanical properties of various B_4C ceramics

Property	Materials		
	HP B_4C[a]	B_4C (5 % C)[b]	BT 60/40[c]
Bulk density, g/cm^3	2.51	2.51	3.30
Flexural strength (4-point, 20 °C), MPa	480	560	730
Knoop hardness	2910	2860	2900
Fracture toughness K_{Ic}, MPa · m$^{1/2}$	2.2	2.1	6.5
Young's modulus, GPa	441	450	480
Mean grain size, µm	5	2	5

[a] Axially hot pressed B_4C with 1.7 wt % free carbon (C_{total} = 21.7 wt % C).

[b] HIP treated sintered B_4C with 4 wt % free carbon.

[c] HIP treated sintered B_4C – TiB_2 composite with 40 vol % TiB_2.

The average coefficient of thermal expansion is 4.6 × 10^{-6}K^{-1} over the range 25 – 800 °C, i.e., almost identical with that for pure SiC ceramic. The coefficient of thermal expansion as a function of temperature (t in °C) is

$$\alpha = 3.016 \times 10^{-6} + 4.30 \times 10^{-9}\, t - 9.18 \times 10^{-13}\, t^2$$

Thermal conductivity decreases with temperature:

t, °C	25	200	400	600	800
λ, W m^{-1} K^{-1}	35	28	23	19	16

However, B_4C has low resistance to thermal shock [30].

Boron carbide is a high-temperature *p*-type semiconductor. The width of the forbidden band is 0.8 eV. The electrical conductivity depends on the B : C ratio and impurity content. The specific electrical resistance of B_4C is 0.1 – 10 Ω · cm, i.e., of the same magnitude as that of SiC and graphite [4], [31]. Boron carbide has a negative temperature coefficient of resistivity, similar to other ceramic materials. Boron carbide is notable for its high thermoelectric power, which increases with temperature [5]. Electronic properties, i.e., electric conductivity, thermoelectric power, and the Hall effect, were measured as a function of B : C ratio by WERHEIT et al. [14]. A metal – insulator transition occurs at the composition B_4C.

The nuclear properties of boron carbide are such that it is a very effective neutron absorber in most types of reactors [4]. The effectiveness of boron as a neutron absorber is due to the large cross section of the ^{10}B isotope (≈ 4000 b). The natural abundance of ^{10}B is 19.9 ± 0.3 mol %. The (n, α) reaction

$$^{10}_{5}B + ^{1}_{0}n \rightarrow ^{4}_{2}He + ^{7}_{3}Li + 2.97\,keV$$

produces helium plus lithium — and no radioactive nuclei. (In contrast, cadmium or the lanthanides do produce radioisotopes.) In addition, the secondary gamma radiation is so small that it can be ignored. The cross section is a linear function of the neutron energy and follows a 1/v relation. The cross sections of boron over the entire neutron energy spectrum, 0.01 – 1000 eV, are sufficiently large to make boron effective in thermal, intermediate, and fast reactors.

1.4. Chemical Properties

Boron carbide is one of the most stable compounds. It is not dissolved by mineral acids or aqueous alkali; however, it is decomposed slowly by mixed hydrofluoric – sulfuric acid or hydrofluoric – nitric acid. One technique of refining B_4C from free carbon and boron is based on the differing oxidation rates of the parent elements and boron carbide. The boron carbide powder is heated in a mixture of H_2SO_4, HNO_3, $HClO_4$, and $K_2Cr_2O_7$ [32].

Molten alkali decomposes boron carbide to give borates. Boron carbide reacts with many metal oxides at elevated temperature to give carbon monoxide and metal borides. Boron carbide reacts with many metals that form carbides or borides at 1000 °C, i.e., iron, nickel, titanium, and zirconium. Aluminum [9] and silicon [33] form substitutional compounds with boron carbide. Boron carbide withstands metallic sodium fairly well at 500 °C [34] but is slowly etched by hydrogen at 1200 °C. At that temperature it does not interact with sulfur, phosphorus, or nitrogen. Above 1800 °C it reacts with nitrogen to give boron nitride. Elemental carbon can be dissolved in B_4C at the B_4C – C eutectic temperature of about 2400 °C, precipitating again on cooling [20].

Chlorine attacks B_4C at about 600 °C and bromine attacks it at 800 °C and above. These reactions can be used to prepare boron halides. Boron carbide can be melted without decomposition in an atmosphere of carbon monoxide, but it reacts in the temperature range 600 – 750 °C with CO_2 to form B_2O_3 and CO. Oxidation in air starts at 500 °C and is severe at 800 – 1000 °C. However, the oxidative damage depends to a great extent on the surface area of the object, powder being attacked more severely than bulk samples.

Detailed descriptions of chemical, mass spectrometric, and spectrochemical analysis of boron carbide have been issued by the American Society for Testing and Materials (ASTM) [35].

Etching methods for polished sections for microstructural inspections of dense boron carbide materials are described thoroughly by PREDEL et al. [36].

1.5. Production

Powder. The most common method for large-scale production of boron carbide is *carbothermic reduction* of boric oxide:

$$2\,B_2O_3 + 7\,C \rightarrow B_4C + 6\,CO$$

The process is so strongly endothermic, 1812 kJ/mol or 9.1 kWh/kg, that it is usually carried out at 1500 – 2500 °C in an electric furnace. Either arc furnaces or resistance furnaces, analogous to Acheson furnaces for SiC, are used [4]. The starting material is an intimate mixture of boric oxide and carbon, e.g., petroleum coke or graphite. Large quantities of carbon monoxide, 2.3 m^3/kg, are generated, and boron can be lost by evaporation of B_2O_3 at the high temperatures. In the electrothermic process used by ESK, a subsidiary of Wacker Chemie, the product is cooled, and the unconverted outer-zone material is removed to leave a fused coarse-grained boron carbide of high purity: B plus C ≥ 99 wt %, total metal impurity ≤ 0.2 wt %, N plus O ≤ 0.3 wt %, B : C mole ratio of 4.0 – 4.3. This boron carbide is obtained in the form of regular blocks, which are broken up and milled to produce the B_4C grain size appropriate for final use.

If the carbothermic reduction is carried out below the melting point of B_4C, e.g., at 1600 – 1800 °C, in a vented graphite tube furnace starting from a dehydrated mixture of H_3BO_3, acetylene black or sugar, and ethylene glycol, very fine-grained (0.5 – 5 µm), stoichiometric B_4C powders are produced [37], although productivity is low.

Uniformly sized submicrometer powders of boron carbide (specific surface area 20–35 m^2/g) can be synthesized continuously by rapid carbothermic reduction (RCR) of boron oxide in a graphite transport reactor at ca. 2000°C [38], [39].

Boron carbide powders are produced directly (no need for the expensive comminution) by magnesiothermic reduction of boric oxide in the presence of carbon at 1000 – 1800 °C:

$$2\,B_2O_3 + 6\,Mg + C \rightarrow B_4C + 6\,MgO$$

This reaction is strongly exothermic. It is carried out either directly by point ignition (thermite process) or in a carbon tube furnace under hydrogen [40]. The product is washed free of magnesium oxide and unconsumed magnesium metal with hydrochloric or sulfuric acid and can be further purified by heating under vacuum at 1800 °C. Since the MgO acts as a grain growth inhibitor, ultrafine boron carbide particles on the order of 0.1 – 1.5 µm are obtained.

There are other methods of powder preparation:

1. synthesis from the elements

   $$(4+x)B + C \rightarrow B_{4+x}C$$

2. reduction of boron trichloride by hydrogen in the presence of carbon

   $$4\,BCl_3 + 6\,H_2 + C \rightarrow B_4C + 12\,HCl$$

3. chemical vapor deposition [41]

   $$4\,BCl_3\,(BBr_3) + CH_4 + 4\,H_2 \rightarrow B_4C + 12\,HCl(Br)$$

However, these methods are generally used only on the laboratory scale for preparing high-purity boron carbide crystals or coatings [4].

Dense Shapes. Self-bonded [42] boron carbide shapes having 100 % theoretical density, small final grain size, and high mechanical strength can be produced by *hot pressing* [43]. This is accomplished by placing a loose powder or a compact preform in a graphite die and applying uniaxial pressure of 10 – 30 MPa at a temperature exceeding 2000 °C for 5 – 10 min. Inert or reducing atmospheres are necessary to protect B_4C and the graphite from oxidation. Increasing the boron content to the composition $B_{13}C_2$ has been found to facilitate sintering by reducing the necessary temperatures and to almost double the strength [44]. However, for boron-rich $B_{4+x}C$ compositions, expensive boron nitride-lined graphite molds must be used, to avoid carburization resulting in formation of carbon-rich B_4C [45].

In 1977, ESK developed a process for *pressureless sintering* of boron carbide, a process now used in everyday production [46]. The key observation, that carbon additives are extremely effective in inducing densification of B_4C, was also made by HENNEY, JONES [47] and SUZUKI et al. [48] almost simultaneously. There are two necessary conditions for obtaining a high sintered density:

1. The use of submicrometer B_4C powders, i.e., powders with a mean particle size below 1 µm
2. The use of small amounts of elemental carbon-containing additive (novolac resin), which pyrolyes to amorphous carbon during the heating cycle [29]

Up to the early 1990s, the carbon was added almost exclusively as novolac resin. However, after an improved method of dispersing carbon black (particle size 20 nm) was developed, the resin route was replaced by the carbon black method [49]. Using nanosized carbon black as sintering aid gives a better sintering behavior with very fine grained materials (mean grain size of B_4C = 1 – 4 µm) having an approximate composition of 96 wt % B_4C and 4 wt % C. The properties of sintered B_4C can be improved further by near net shape injection molding [50] and post-HIPing (HIP, hot isostatic pressing) after pressureless sintering [50], [51]. In this post-HIP stage, the sintered shapes are densified to > 99.5 % TD at 1950 – 2050 °C in a high-pressure autoclave (≥ 10 MPa).

The pressureless sintering/HIP route has also been used to prepare B_4C – SiC composites [52], [53] and B_4C – TiB_2 composites [54], [55]. The B_4C – SiC composites combine the good thermal shock and oxidation resistance of silicon carbide with the hardness and low density of boron carbide. In this way, a maximum strength of 550 MPa (four-point bend) was achieved for a composite of 59 wt % SiC, 37 wt % B_4C and 4 wt % C. This composite can be used in oxidizing atmospheres up to 1200 °C [52]. Excellent tribological and wear properties were obtained by KEVORKIJAN et al. [53] for B_4C – SiC composite materials, which suggest their use for heavily loaded mechanical seals and bearings.

The newly developed B_4C – TiB_2 composite materials [54], [55] are electroconductive and combine excellent fracture toughness (see Figure 3), with the high hardness of boron carbide (Table 2). They are used as nozzle materials for hard alumina grits in abrasive air-jet cleaning in dental laboratories. While the above-mentioned composite materials are formed by mixing the desired metal boride phases and subsequent sintering, processes have also been described in which the desired metal boride composition is only formed after a suitable reaction of the starting materials during the sintering step. SKOROKHOD and KRSTIC [56] fabricated a 85 vol % B_4C – 15 vol % TiB_2 composite with a flexural strength of 621 MPa and a fracture toughness of 6.1 MPa · $m^{1/2}$ (measured by the SENB method with 100 µm notch width) by reaction hot pressing of a boron carbide powder with submicrometer particle size using additions of submicrometer-sized TiO_2 and carbon at 2000°C. The formation of uniformly distributed TiB_2 particles (< 5 µm grain size) was in accordance with the reaction.

$$(1+x)B_4C + 2TiO_2 \rightarrow xB_4C + 2TiB_2 + 4CO$$

Another approach to produce tough and high-strength B_4C ceramics is liquid-phase sintering. LEE and KIM [57] showed that addition of alumina (Al_2O_3) promotes densification of boron carbide, and a maximum density of 96% of theoretical can be obtained with 3 wt % alumina-doped B_4C sintered at 2150°C, i.e., above the melting point of Al_2O_3. The microstructure showed equiaxial B_4C grains with a mean grain size of about 7 µm. However, when the addition of Al_2O_3 exceeded 3 wt %, exaggerated grain growth occurred, which was attributed to the liquid phase. It has been reported [58] that by hot pressing of B_4C with alumina additions of up to 5 vol % at 2000 °C the mechanical properties can be remarkably increased as compared to undoped, hot-pressed B_4C of 88 % relative density. Fracture toughness increased steadily with the addition of Al_2O_3 from ca. 3 MPa · $m^{1/2}$ (2.5 vol % Al_2O_3) up to 3.8 MPa · $m^{1/2}$ (10 vol % Al_2O_3). However, the achieved flexural strength was below 560 MPa.

The fracture toughness of boron carbide can be improved by addition of yttria [59] or of yttria in combination with other oxides [60]. The fracture toughness of B_4C can be increased to 3.9 MPa·$m^{1/2}$ by vacuum sintering at 1900 – 1975°C of powder compacts of composition 97.5 wt % B_4C and 2.5 wt % carbon packed in a yttria grit of 0.15 – 1.4 mm grain size [59]. The vacuum allows yttria vapor to penetrate the powder compact and promote reaction sintering of carbon-doped B_4C to full density (2.62 g/cm^3). X-ray diffraction showed that yttrium boride and yttrium borocarbide were coexistent with B_4C. The method disclosed in [60] uses liquid-phase sintering under vacuum or streaming argon of powder compacts comprising B_4C powder (average particle size 0.6 – 3.5 µm) and 1 – 28 wt % additions of Y_2O_3 in combination with Al_2O_3 or aluminum nitride (AlN) and La_2O_3 or CeO_2.

Figure 3. Fracture toughness of B_4C – TiB_2 composites and self-bonded B_4C as a function of free carbon content

60/40 and 80/20 indicate B_4C/TiB_2 vol % in the starting mixture [54].

1.6. Uses

The uses of boron carbide are described in [4-6], [30], [31], [61].

Uses Based on Hardness. The major industrial use of boron carbide is as abrasive grit or powder. Commercial grits are available in particle sizes from 1 µm to 10000 µm and predominantly used as polishing, lapping, and grinding media for hard materials, especially cemented tungsten carbide and fine ceramics. Water and commercial oils serve as lubricant and coolant. Available as a substitute for loose powders is B_4C paste, which can withstand temperatures up to 350 °C.

The second category is wear-resistant engineering components made of dense, sintered shapes. Boron carbide sand-blasting nozzles are now the most common form of such a component. These nozzles are characterized by minimum wear, even with corundum or silicon carbide grit. Sintered-B_4C

wheel dressing sticks are used to produce new cutting edges on surface grains of grinding wheels with minimum wear. So-called hand laps are used to render the cutting edges of cemented carbide tools keen and smooth. Mortars and pestles of boron carbide are suitable for grinding hard materials without contamination from the grinding equipment.

Ultrahard substances are nonductile. This factor, together with a density of only 2.5 g/cm^3, is fully exploited in the use of dense B_4C as ceramic plates against armor-piercing bullets of caliber up to the thickness of the plates [61]. Lightweight ceramic tiles have been used extensively for the protection of helicopters; monolithic breastplates, for the protection of personnel [62], [63]. Hot pressings made from a finer grade of boron carbide are used in air bearings of inertial navigation equipment.

Uses in Nuclear Technology [30], [64]. Boron carbide is both cheaper and easier to fabricate than the element boron itself. As a result it has found almost exclusive usage as a control rod material, neutron poison, and a neutron shielding material. The bulk density of vibro-packed B_4C powder, better the sintered density of self-bonded boron carbide pellets, or the ^{10}B : ^{11}B ratio can be varied to adapt absorber efficiency to the specific conditions in thermal (BWR, PWR), high-temperature (HTR), and fast breeder reactors (FBR).

A ^{10}B-enriched boron carbide, e.g., corresponding to ≤ 92 mol % ^{10}B, is commercially available; thus, the nuclear worth of an absorbing element can be increased nearly 4.5-fold by substituting enriched for natural material, without a change in dimensions. The helium formed during reactor exposure is partially retained within the solid B_4C as micropores, but the fraction released (≦ 50 %) must be accommodated by some aspect of control assembly design, such as a plenum within an individual pin or a reliable pressure relief vent. The He and Li atoms, because of their relatively large size, cause some radial swelling (≦ 10 %) of the B_4C pellets.

In a typical thermal reactor the operating temperature of the absorber is below 500 °C, and low-density (ca. 75 % of theoretical density) B_4C pellet columns clad in metal sheets have proved adequate for large-scale commercial use. In gas-cooled reactors, boronated graphite containing about 40 wt % B meets the high-worth control rod requirements. Ceramic-based dispersions, i.e., combinations of relatively small amounts of B_4C in an inert matrix, exhibit smaller macroscopic neutron absorption cross sections but swell less and release less gas. So-called burnable poison rods, which are consumed at the same rate as the fuel, are commonly designed in this fashion. Examples are Al_2O_3 – 3 vol % B_4C for water-cooled reactors and boronated graphite (ca. 6 wt % B_4C) for gas-cooled reactors.

^{10}B-enriched B_4C has been chosen as the absorber for fast-breeder reactor control material. A potential alternative for future fast breeder generations is ^{10}B-enriched europium hexaboride, which has better engineering properties and which loses its absorption reactivity because of ^{10}B burnup about 40 % slower than B_4C [65]. Carbon-bonded boron carbide plates (TETRABOR®) [66] provide for the closest possible arrangement of spent fuel elements in high density intermediate storage pools. Sizes range up to 500 mm in length and down to 2 mm in thickness. These shield plates with > 50 vol % B_4C usually contain more absorber material than aluminum-bonded B_4C (Boral) and silicone-bonded B_4C plates (ESK-Elastosorb). Doors, windows, or walls in laboratories where radioactive matter is investigated are screened with B_4C plates. Their low density of ca. 1.6 g/cm^3 makes them excellent for lining containers for nuclear fuel or any matter radiating neutrons.

Chemical Uses. Boron carbide powder is used to introduce boron into the surface layer of steels and other ferrous materials [31], [67]. This takes place by diffusion of boron into the surface layer, resulting in the formation of a thin (10 – 1000 µm) but hard, wear-resistant layer of iron boride, Fe_2B. Vickers hardness numbers of 2400 HV-0.1, corresponding to tungsten carbide or α-Al_2O_3, were measured on the surface of high-alloyed tool steels. The surfaces of cemented carbides (WC–Co, WC–TiC–TaC– Co/Ni/Fe, and Ferrotic) and stellite alloys can even be hardened further by boron [68]. According to the EKabor powder packing method B_4C – SiC powder mixtures with added sodium tetrafluoroborate activator are used.

Its high boron content makes B_4C useful as a raw material for the production of other boron compounds, including the boron halides and metal borides [4]. Much of the BCl_3 made commercially is used in the production of boron filament for reinforcement of metals and plastics. The exceptionally high heat of combustion of B_4C makes powders with a mean particle size of 2 µm useful energy carriers in solid rocket propellants [4].

Uses in Refractories. In carbon-bonded refractories, B_4C powder is used as an antioxidant. Small additions of B_4C to the refractory material reduce the burn out of the carbon and improve the corrosion resistance against slags and steel melts. A simultaneous addition of B_4C and a metallic antioxidant results in better oxidation resistance of the refractories than the addition of B_4C or the metallic antioxidant alone [69], [70]. The effect depends on the oxidation of the antioxidants and reaction with the oxides of the refractory material, which creates oxidic phases and gaseous components. Both prevent the infiltration of molten slag or steel, and the oxide phases protect the carbon against oxidation by forming a protective oxidic layer at the hot face of the refractory.

Uses in Metal Matrix Composites. Metal matrix composites (MMCs) made of B_4C and Al or Al-alloy have a higher stiffness, strength and hardness and lower weight than the metal itself. The content of B_4C in the MMCs is up to 50 wt %. This material could be used to produce magnetic disks for hard disk drives, automotive components, sports goods, etc. [71-73].

Other Uses. The thermoelectric properties of $B_{13}C_2$ [74] are such that $B_{13}C_2$ could be an interesting material for high-temperature thermoelectric conversion. Thermoelements made of the couple B_4C – C can be used for temperature measurements up to 2300 °C [75].

1.7. Economic Aspects

ESK is the world's largest producer of boron carbide. The granular and sintered B_4C products of this company are sold commercially under the trademark TETRABOR®. The price of B_4C is 10 – 150 $/kg, depending on grit size. Annual world production is about 3500 t.

[Top of Page]

2. Boron Nitride

The elements boron and nitrogen, both neighboring carbon in the periodic table, form the 1 : 1 compound BN [10043-11-5], which has allotropes isostructural to the allotropes of carbon:

1. Alpha-BN, hexagonal modification with a layered structure similar to graphite, sometimes called white graphite
2. Beta-BN, high-pressure diamond-like modification, cubic zinc blende structure
3. Gamma-BN, dense hexagonal modification, wurtzite structure

More detailed reviews of the properties, preparation, and uses of the various BN modifications are given in [76-78], [63].

2.1. Properties

α-BN. The most common form of boron nitride is the graphitelike hexagonal, used increasingly because of its unique combination of properties: low density, 2.27 g/cm^3; high-temperature stability, *mp* near 3000 °C; chemical inertness, especially its resistance to acids and molten metals and its stability in air up to 1000 °C and in inert gases like N_2, CO, and Ar up to 2700 °C; stability to thermal shock; workability of hot-pressed shapes; extremely low electrical conductivity, which makes it an excellent insulator; and high thermal conductivity.

In *thermal conductivity* BN ranks with stainless steel at cryogenic temperatures and with beryllium oxide, BeO, at higher temperature. Above 700 °C the thermal conductivity of α-BN exceeds that of BeO. Boron nitride has a dielectric constant of 4, one half that of α-Al_2O_3, which also has high dielectric strength. It is a lubricant over a wide range of temperatures; its low coefficient of friction is retained up to 900 °C, whereas other solid high-temperature lubricants, e.g., graphite and molybdenum disulfide, burn away well below 900 °C [80].

Because of its *stability* at high temperature and inertness towards carbon and carbon monoxide up to 1800 °C, it is used as a refractory ceramic. In this function it is superior to the nitride ceramics Si_3N_4 and AlN and the oxide ceramics MgO, CaO, and ZrO_2. It is not wet by and thus is stable against attack by molten glass, molten silicon, boron, nonoxidizing slags, molten salts such as borax and cryolite, and reactive molten metals, including aluminum, iron, copper, and zinc. Because it sinters poorly, dense shapes of α-BN are produced exclusively by hot pressing. Two material types are important for practical applications

1. Shaped bodies of pure hexagonal BN
2. Shaped bodies of hexagonal BN with addition of refractory oxides, carbides and nitrides with BN contents ≥ 20 wt % (composite ceramics)

Typical properties of hot-pressed BN and BN – ZrO_2 composite ceramics are summarized in Table 2.

Table 2. Property data on boron nitride ceramics

	Hot-pressed BN	Hot isostatically pressed BN	Hot-pressed composite ceramics BN/ZrO_2
Bulk density, g/cm^3	2.0	2.2	2.8 – 3.6[b]
Porosity, vol %	< 7	< 1	< 7
Modulus of rupture (4-point), [a] MPa	100/80	50	130/70
Young's modulus, [a] GPa	70/35	30	80/35
Thermal conductivity, [c] $Wm^{-1}K^{-1}$			
20 °C	65/45	50	35 – 25/20 – 18 [b]
400 °C	50/30	40	31 – 21/17 – 15
700 °C	30/20	30	28 – 18/15 – 13
1000 °C	15/10	20	25 – 15/13 – 18
Thermal expansion coefficient, [a] 10^{-6} K^{-1} (at 20 – 1000 °C)	1.2/8.0	4.0	4.5 – 9.0/8.5 – 11.0 [b]
Specific heat, J/gK (at 20 °C)	0.8	0.8	0.7
Electrical resistivity, Ωcm (at 20 °C)	> 10^{12}	> 10^{12}	> 10^{12}
Dielectric strength, kV/mm (at 20 °C)	> 6	> 6	> 6

[a] Test orientation vertical/parallel to pressing direction.
[b] Dependent on BN/ZrO_2 ratio.

Most chemical and physical properties of axial hot-pressed BN shapes depend on the nature and amount of densification additives (≤ 5 wt % B_2O_3 or metal borates) [77]. In addition, the coefficient of expansion and thermal conductivity as well as the flexural strength and Young's modulus are *anisotropic;* they vary with the direction of hot-pressing. In this respect, BN is similar to graphite. However, isostatic hot-pressing (HIP) of canned BN powder, produces pure isotropic α-BN shapes of theoretical density. Such shapes possess superior thermal and mechanical properties (see Table 2) [81].

β-BN. The cubic form of boron nitride, β-BN, the commercial Borazon, resembles diamond in crystal structure and other properties. Pure β-BN is colorless and a good electrical insulator. Doping with Li_3N or the elements Be, Si, C, or P turns β-BN yellow to black and changes other properties, such as conductivity or toughness.

The theoretical density of β-BN is 3.48 g/cm^3. The Knoop hardness number HK-0.1 is ca. 4700, somewhat less than the > 7000 for diamond. Because β-BN is stable in air up to 1400 °C — diamond burns away at only 800 °C — it is an effective high-temperature abrasive.

γ-BN. Wurtzite boron nitride, γ-BN, which is metastable at the pressures and temperatures where β-BN is fabricated, has a density close to cubic β-BN. Above 5.5 GPa and 1300 °C γ-BN transforms to cubic β-BN [82].

2.2. Production

Hexagonal α-BN was prepared for the first time by BALMAIN [83] in the middle of the nineteenth century. It remained a laboratory curiosity until the mid-1900s, when hot-pressed α-BN shapes were made for the first time [84]. Although there are a number of general methods of producing *powder* [76], principally two reactions are used on an industrial scale:

1. Reaction of boric oxide or boric acid with ammonia in the presence of a carrier, often tricalcium orthophosphate:

$$B_2O_3 + 2\,NH_3 \xrightarrow{900\,°C} 2\,BN + 3\,H_2O$$

   A second heat treatment for purification and stabilization is carried out > 1500 °C under N_2.
2. Reaction of boric acid or borax with organic nitrogen compounds, e.g., urea or melamine:

$$B_2O_3 + CO(NH_2)_2 \xrightarrow{>1000\,°C} 2\,BN + CO_2 + 2\,H_2O$$

Method 1 usually gives crystalline α-BN in the form of thin hexagonal platelets with a thickness of about 0.1 – 0.5 µm and a diameter of up to 5 µm. Method 2 can give a “turbostratic” boron nitride, a hexagonal structure characterized by partial or complete absence of three-dimensional order among its lamellae [85], [86].

Dense α-BN is produced in two ways:

1. Axial hot-pressing [84] or hot isostatic pressing [81] of fine powders to give billets that can be easily machined
2. Pyrolysis of a boron trichloride – ammonia mixture,

   $$BCl_3 + NH_3 \rightarrow BN + 3\,HCl$$

   on a graphite substrate on which the α-BN is deposited.

Pyrolytic BN, though pore-free and impervious to helium, is anisotropic because the α-direction layer planes of the hexagonal structure deposit parallel to the substrate surface [87]. α-BN is also available in the form of fibers [88], thin films [89], and multidimensional fiber infiltrated BN – BN composites [90].

The cubic zinc blende form of boron nitride was first prepared from the graphitic form by applying pressures of 4 – 6 GPa (40 – 60 kbar) at 1400 – 1700 °C in the presence of a lithium or magnesium nitride catalyst [91]. Later, the use of the ternary compound $Ca_3B_2N_4$ as the catalyst has been proposed to produce β-BN crystals of outstanding purity, quality, and size (0.1 – 0.3 mm) [92]. Details of the various high-pressure, high-temperature (HP-HT) syntheses and low-pressure syntheses for β-BN can be found in [63]. Deposition of β-BN coatings, mainly produced by PVD and plasma CVD methods, has been investigated. Due to the difficulties of growing large β-BN crystals and depositing thick layers, the low-pressure sintering method is not commercially used today.

Cubic BN particles can be sintered into strong masses at the high temperatures and high pressures at which this diamond-like form is stable [93]. Also starting from shock-synthesized γ-BN of 0.1 – 0.5 µm particle size and hot pressing at 6.7 GPa and 1600 °C produces self-bonded compacts of theoretical density and predominantly cubic structure, 80 % β – 20 % γ-BN [82].

Wurtzite-type boron nitride, γ-BN, can be obtained by static compression above 6.0 GPa or by dynamic compression at 12 – 13 GPa below 1700 °C [94], [95].

2.3. Uses

The many uses for α-BN powder and hot-pressed shapes are summarized in Table 3, which classifies specific properties. As can be seen from this table, α-BN has established itself in the various fields of chemistry, metallurgy, high-temperature technology, electrotechnics, and electronics. α-Boron nitride powder is also available in the form of coating suspensions and as a convenient aerosol spray. Annual world production of α-BN powder is ca. 1000 t (ca. 2005); the price of α-BN is 30 – 100 $/kg.

Table 3. Uses and potential uses for α-boron nitride

Use	Property desired					
	R	T	E	I	L	M
α-BN powder						
Solid lubricant for high-temperature bearings	+				+	
Mold release for die casting of glass and metals	+			+	+	
Active filler for rubber, resins, and plastics	+	+	+	+	+	
Additive to oils and high-temperature greases				+	+	
Ultrahigh-pressure transmitting agent	+			+	+	
Coatings for evaporation plants, as parting agent for deposited metal films	+			+		
Raw material for β-BN	+					
Component for cosmetic applications				+	+	
Coatings of tundishes for nonferrous metals	+				+	
Mold release for injection molding of plastics					+	
Coating for graphite hot-pressing molds	+			+	+	
Embedding medium for heating wires	+		+	+		
Boron source for preparation of other boron compounds	+					
α-BN hot-pressed shapes						
Crucibles for melting glass and metals	+	+		+		+
Break rings for horizontal continuous casting of high-alloy steels	+			+	+	+
Break rings for low-alloy steels	+			+	+	+
Spanker plates used in the production of TV tubes	+			+		+
End-dam material for thin-strip casting	+			+	+	+
Seal rings for gas sensors (lambda sensor)	+		+	+		+
Components for high-temperature electric furnaces	+	+	+	+		+
Structural parts for magnetohydrodynamic devices (MHD)	+		+	+		+
Dielectric for radar antennas and windows			+			+
	+		+			+

Insulators for low- and high-frequency equipment						
Insulators for plasma-jet furnace, arc pulse generators, and ion engines	+		+			+
Holders, mounting plates, substrates, and heat sinks in valve and transistor circuits		+	+			+
Pump components, pipes, and nozzles for handling liquid metals	+			+		+
Protective tubes and insulating sleeves for thermocouples	+	+	+	+		+
Protective sleeves for electrodes in automatic welding	+		+	+		+
Wafers for boron doping of semiconductors	+					+
Molds for hot-pressing of ceramics like B_6O or $B_{6.5}C$	+	+		+	+	+
Neutron absorbers and shields for nuclear reactors	+	+		+		+

R high-temperature refractoriness; T thermal conductivity; E electrical insulator; I chemical inertness, nonwetting; L lubricity; M machining ease.

Since cubic boron nitride is the second hardest material after diamond, its uses are similar to those of diamond — machining and drilling. Grinding wheels made from resin- or metal-bonded β-BN grits in many cases are superior and more economical than diamond wheels because of their better chemical resistance and greater toughness. Sintered dense compacts of β-BN are being used increasingly as cutting tools for hard steels and tough nickel-based superalloys, as wire drawing dies, and as cutting heads in rock drills [63]. The longer life of cutting tools containing wurtzite-type γ-BN in addition can be related to the lubrication provided by the α-BN that forms from the less stable γ-BN during cutting [96].

[Top of Page]

3. Metal Borides

Boron combines with a large number of metals and semimetals to form binary or higher solid compounds, the so-called borides. Most binary borides, especially those formed from transition metals having high melting points, are metallic high-temperature materials that can be grouped with the carbides, nitrides, and silicides as refractory hard materials [1], [97]. Although boride cermets [98], [99] that combine the extreme hardness of refractory borides with the high toughness and ductility of a metallic binder have been recently developed, they are far from attaining large-scale application.

Nevertheless, metal borides have some unique properties and are used in some specialized fields of modern industry, especially when the requirements cannot be met by other materials. More information about metal borides is available in [31], [61], [100-108], [109]], [7].

3.1. Properties

Metal borides are unique in the number of stoichiometries; compositions corresponding to at least 24 M : B ratios between 5 : 1 and 1 : 66 are known. However, the most common are the monoborides, MB; diborides, MB_2; tetraborides, MB_4; hexaborides, MB_6; dodecaborides, MB_{12}; and hectoborides, MB_{66}. The binary compounds of boron are given in the form of a periodic table in Table 4. As can be seen, many metal – boron systems contain three or more intermediate phases.

Table 4. Binary compounds of boron

[a] And higher boranes.
[b] Parentheses around a compound indicate that its existence has not been confirmed. Note: high pressure phases are not listed.

A classification of borides was first given by KIESSLING [110] on the basis of boron structural elements typical for various M : B ratios. With increasing M : B ratio the tendency to form boron – boron bonds increases, and pairs (M_3B_2), zigzag chains (MB), branched chains ($M_{11}B_8$), double chains (M_3B_4), plane nets (MB_2), and finally three-dimensional arrays of boron atoms, including cross-linked nets (MB_4), interconnected B_6 octahedra (MB_6), B_{12} cubic octahedra (MB_{12}), and interconnected B_{12} icosahedra (MB_{66}) are all found.

The most characteristic properties of the metal borides are their high melting points, extreme hardness, and in many cases high electrical and thermal conductivities, fair corrosion resistance, good wear resistance, and thermal shock resistances superior to those of oxide ceramics. Some physical properties of the most common and typical metal borides are given in Table 5. The most stable binary borides at high temperatures are the diborides of titanium, zirconium, and hafnium, each melting above 3000 °C. The melting points of the boron-rich borides MB_n, $n \geqq 2$, are generally higher than those of the parent transition metals. On the other hand, melting points of metal-rich borides are often as low as those of their parent metals. Most of these borides are paramagnetic. Knoop hardness numbers HK-0.1 usually fall in the range of 1100 – 2600 for diborides, 1650 – 2100 for hexaborides, and 2300 – 2600 for dodeca- and hectoborides; therefore, many borides are harder than WC or α-Al_2O_3, two cutting and grinding materials widely used. Hardness and high melting points reflect the properties of the rigid, three-dimensional boron frameworks.

Table 5. Physical properties of some refractory borides [61]

Boride	CAS Registry	Density,	Melting	Electrical	Knoop

	no.	10^3 kg/m^3	point K	resistivity, 10^{-8} Ω · m	hardness, 0.1 kp load
TiB_2	[12045-63-5]	4.52	3470	9 – 15	2600
ZrB_2	[12045-64-6]	6.09	3520	7 – 10	1830

CoB	[12006-77-8]	7.32	1535	26	2350
NiB	[12007-00-0]	7.39	1325	23	
LaB_6	[12008-21-8]	5.76	2985	7 – 15	2010
EuB_6	[12008-05-8]	4.91	2890	80 – 170	1840
UB_4	[12007-84-0]	9.38	2768	30	1850
UB_{12}	[12008-80-9]	5.65	2500	22	2630
CaB_6	[12007-99-7]	2.46	2540	160	1650
SiB_6	[12008-29-6]	2.43	2140	2×10^5	2140
B_4C		2.52	2720	$10^5 – 10^7$	3000
β-B		2.35	2420	10^{12}	2600

The electrical characteristics, however, cover the entire spectrum: semiconductors, the MB_{66}, MB_6, and MB_{12} phases of Be, Mg, Ca, Eu, Al, and Si; metallic conductors, TiB_2, ZrB_2, and the majority of transition-metal borides; superconductors, NbB, YB_6, and ZrB_{12}.

In addition, LaB_6 and other lanthanide and actinide borides (YB_6, ThB_6, GdB_6, etc.) belong to the best-known high-temperature electron emitters. Most of these borides are intensively colored: for example, ZrB_{12} is pink, GdB_6 is blue, LaB_6 is purple, and ThB_6 is scarlet [61, 111].

The metal borides display resistance to oxidation in air at elevated temperatures, most of them up to 1000 °C, and to attack by molten metals, basic slags, and molten salts. Except for alkali metal and alkaline earth metal borides, which are saltlike and ionic, they are not readily attacked by nonoxidizing acids and aqueous alkalis. Resistance to oxidation is greatest for the transition metal diborides and is lower for greater boron contents. The controlling factor is the surface layer of parent boron and transition metal oxides, which prevents further oxidation up to temperatures at which boric oxide has appreciable volatility. Most metal borides are inert in hydrogen, nitrogen, and carbon, even at high temperatures. Chlorine and fluorine react vigorously with all borides, fluorine even at 400 °C. All types of borides are readily attacked by oxidizing molten salts such as nitrates and carbonates and hydroxides in the presence of air, and this is a usual method of decomposition for chemical analysis [112].

3.2. Production

Metal borides can be prepared by the following high-temperature reactions [61]:

1. synthesis from the elements by melting, sintering, or hot-pressing
2. borothermic reduction of metal oxides
3. aluminothermic, silicothermic, or magnesiothermic reduction of metal oxide – boric oxide mixture
4. carbothermic reduction of metal oxide – boric oxide mixtures, e.g.,

$$TiO_2 + B_2O_3 + 5\,C \rightarrow TiB_2 + 5\,CO$$

5. reduction of metal oxide with carbon and/or boron carbide, i.e., the boron carbide method, e.g.,

$$2\,ZrO_2 + B_4C + 3\,C \rightarrow 2\,ZrB_2 + 4\,CO$$

$$Eu_2O_3 + 3B_4C \rightarrow 2\,EuB_6 + 3\,CO$$

6. electrolysis of fused salts containing metal oxide and boric oxide
7. auxiliary-metal bath method, M + B being dissolved in molten Al, Cu, Sn, or Pb
8. deposition from the vapor phase involving coreduction of a metal halide – boron halide mixture by hydrogen, optionally as a plasma [113]:

$$TiB_2 + 2\,BCl_3 + 5\,H_2 \rightarrow TiB_2 + 10\,HCl$$

Reactions 1, 2, 6, 7, and 8 give pure products but are almost always restricted to the laboratory. For large-scale production, borides are prepared by reactions 4 and 5 followed by purification. These reactions are usually carried out in electric furnaces much like those for production of boron carbide. Molten metal borides often contain up to 3 wt % carbon and boron carbide, although these impurities can be scavenged with additional metal oxide or boric oxide on reheating the powdered mixture above 1400 °C under a partial vacuum. After cooling, the metal boride is crushed and milled to its final grain size. Monolithic boride shapes usually are fabricated from commercial boride powders by powder metallurgy techniques (⟶ Powder Metallurgy and Sintered Materials):

1. cold forming — isopressing, slip casting, etc. — followed by pressureless sintering of the powder compact [113-116], [117]

2. axial hot-pressing [118-121] and hot isostatic pressing [116], [122] (see Section Production, production of B_4C powder)

TiB_2 – Fe hard metals have been developed to sintered densities above 99 % TD by using fine-grained raw materials and vacuum sintering [98], [123-128]. The microstructure contains some Fe_2B and Ti_2O_3, which can be avoided by additions of Ti or TiH_2. The interesting strength, toughness and hardness properties of these materials (see Figure 4) suggest some future applications.

Figure 4. Hardness and fracture toughness of TiB_2 – Fe hard metals compared with commercial hard metals [129]

Cemented ternary transition metal borides have also been developed based on, e.g., $Mo_2(Fe, Ni)B_2$ as the hard phase sintered with iron metals (Fe, Ni, Co). Especially the Mo_2FeB_2-base cermet shows excellent wear behavior [130], [131]. Mo_2NiB_2 cermets were produced from a Mo_2NiB_2-type complex boride as a hard phase and a Ni-base binder by a novel sintering technique, named *reaction boronizing sintering*. The phase transformation of the Mo_2NiB_2-type complex boride from orthorhombic to tetragonal with optimal addition of Cr and V was essential for improvement of the mechanical properties (flexural strength, 2.5 GPa; Rockwell A hardness, ca. 90) and microstructural refinement of the cermet [99].

3.3. Uses

The principal use for metal diborides is as a crucible material for nonferrous metals, especially for aluminum, copper, magnesium, zinc, tin, and lead. Monolithic shapes of dense TiB_2 [132] are used for the electrolytic production of aluminum with the Hall – Héroult cell [133]. Hot-pressed TiB_2 armor plates are used in the protection of ground-based military vehicles. Their inertness to molten aluminum and cryolite and excellent electrical conductivity suggest titanium diboride and zirconium diboride as cathode leads, electrodes, and thermocouple sheaths in aluminum metallurgy [134]. Related uses are TiB_2 – BN or TiB_2 – BN – AlN hot-pressed composite crucibles, so-called evaporation boats, for the continuous evaporation of aluminum metal for vacuum metallizing [135]. The composites show high corrosion resistance against molten metals and good electrical conductivity (TiB_2 has high electrical conductivity). The crucibles/boats are heated in direct current, and by varying the BN content the electrical conductivity of the boats can be controlled. Coatings of BN are used in a wide range of applications due to the extraordinary properties of BN. They are used in the aluminum and steel industries to enhance corrosion resistance and reduce wear on sliding parts like crankshafts for compressors. Because of the nonwettability of BN against many metallic and nonmetallic melts various parts are often coated with BN, e.g., silicon in the semiconductor industry, or BN is used for linings to prevent reactions with Si or Al. Coatings can be produced by CVD techniques to obtain well-crystallized linings with relatively high strength. Also BN layers can be produced by spraying, brushing, dipping, and pouring. The coatings provide improved high-temperature electrical insulation for the semiconductor industry. In molding equipment BN coatings reduce sticking and reactions between powder and mold. High-temperature lubrication properties are important in aluminum and steel manufacturing processes such as casting. On BN-coated preforms, metal layers can be deposited and easily peeled off to give free-standing metal sheets. BN coatings on SiC or Al_2O_3 fibers reduce the thermal mismatch between fiber and matrix and also reduce fiber – matrix interfacial shear strength in ceramic matrix composites to give higher overall strength and toughness [63].

TiB_2 – Fe cermets are suitable for machining aluminum alloys [129], whereas ternary boride cermets based on Mo_2FeB_2, Mo_2NiB_2 and WCoB are suitable as machine parts for injection molding, bearings, wire-drawing cones, and cutting tools [99], [131]. The world production of TiB_2 is ca. 250 t/a, much of this for the manufacture of these resistance-heated evaporation boats. The price of TiB_2 powder is 30 – 60 $/kg.

Calcium hexaboride, CaB_6, is used as a deoxidizer for high-conductivity copper [136-138]. CaB_6 and ZrB_2 are used as antioxidants in carbon-bonded refractories (cf. Uses in Refractories.). For ZrO_2 – C submerged nozzles used in the continuous casting of aluminum a partially or total change of ZrO_2 to ZrB_2 at the powder can more than double corrosion resistance [139]. A major use of NiB, CrB, and CrB_2 is the production of welding and hard-facing alloys based on nickel – chromium – boron – silicon, called colmonoy [140]. An iron – boron alloy 85 wt % Fe/15 wt % B is used to introduce boron into steel (at about 0.002 wt %) in order to improve hardenability [141]. The ternary boride $Fe_{14}Nd_2B$ has been developed for use as a magnetic material (⟶ Magnetic Materials) [142].

The hardness and wear properties of borides are utilized economically as thin coatings on metal surfaces, prepared by the so-called boronizing process (cf. the chemical uses of B_4C in Chemical Uses.). Lanthanum hexaboride is useful as a high-current-density electrode for electron microscopes, electron-beam furnaces, and other devices of highest electronic emissivity. The lifetime of LaB_6 electrodes is reported to exceed that of tungsten cathodes by two orders of magnitude [143, 144].

The refractory hexaboride of europium was suggested as a neutron absorber to control the power of fast breeder reactors. As a neutron absorber EuB_6 is equivalent to 35 mol % ^{10}B-enriched boron carbide, and its nuclear worth is ca. 15 % higher than europium sesquioxide [30], [64], [65].

1. Boron Halides

1.1. Physical Properties

Boron forms trihalides, sometimes called trihaloboranes, with fluorine, chlorine, bromine, and iodine. The trifluoride [*7637-07-2*], BF_3, M_r 67.80, and trichloride [*10294-34-5*], BCl_3, M_r 117.19, are gases at room temperature. The tribromide [*10294-33-4*], BBr_3, M_r 250.54, is a liquid, and the triiodide [*13517-10-7*], BI_3, M_r 391.52, is a solid. All four trihalides are colorless, but the tribromide and triiodide discolor on exposure to light. A summary of some physical properties of these compounds is given in Table 1 (see next page).

All four compounds have trigonal symmetry with X−B−X angles of 120°. A crystal structure has been reported for a metastable phase of BF_3 at 142 K in which boron atoms are trigonal prismatic with $B-X_{eq}$ bond lengths of 0.126 – 0.131 nm and $B-X_{ax}$ bond lengths of 0.268 – 0.271 nm [10].

1.2. Chemical Properties

Trivalent boron halides are coordinatively unsaturated and their chemistry is dominated by the unfilled boron p_z orbital. The compounds are Lewis acids and readily form adducts with a variety of electron donors. Overlap of the unfilled boron p_z orbital with nonbonding filled orbitals

on the halides decreases the electron acceptor ability of the molecule but increases the strength of the B−X bonds. The B−F bond in BF_3 is the strongest single bond known. The boron – halide p_z overlap decreases with increasing size of the halide. Thus, the acceptor strength increases as $BF_3 < BCl_3 < BBr_3 < BI_3$. However, the strength of the B−X bond decreases from BF_3 to BI_3. Boron trifluoride chemistry is dominated by Lewis acid – base reactions, whereas BBr_3 and BI_3 adducts are relatively unstable and halide displacement reactions predominate.

1.2.1. Exchange Reactions

All of the boron halides undergo halide exchange reactions, but of the mixed halide species only BBr_2I and $BBrI_2$ have been isolated. Exchange reactions are also known with trialkyl-, triaryl-, trialkoxy-, and triaryloxyboranes:

$$BX_3 + 2\,BR_3 \longrightarrow 3\,BXR_2$$

Exchange reactions between BF_3 and metal halides may be used to prepare other boron trihalides:

$$3\,KCl + 4\,BF_3 \longrightarrow 3\,KBF_4 + BCl_3$$
$$AlBr_3 + BF_3 \longrightarrow BBr_3 + AlF_3$$

1.2.2. Halide Displacement Reactions

Boron halides, with the exception of boron trifluoride, react readily with compounds that have active hydrogen atoms, including water, alcohols, thiols, amines, phosphines, and arsines. Because of the strength of the boron – fluorine bond, halide displacement reactions occur to a lesser extent with BF_3 than with other boron halides. Boron trifluoride reacts with water to give a number of partially hydrolyzed fluoroborate species including BF_3OH^-, $BF_2(OH)_2^-$, and $BF(OH)_3^-$, in addition to boric acid and the fluoroborate anion, BF_4^-. Two hydrated species, $BF_3 \cdot H_2O$ and $BF_3 \cdot (H_2O)_2$, can be isolated at low temperature. The dihydrate is formulated as $BF_3OH_2 \cdot H_2O$ [11].

In contrast to the slow substitution reactions of BF_3, other boron trihalides react vigorously with water:

$$BX_3 + 3\,H_2O \longrightarrow B(OH)_3 + 3\,HX$$

The reaction of BBr_3 or BI_3 with water may be explosive.

Most halide displacement reactions with BF_3 require either elevated temperature or an active nucleophile, such as a Grignard reagent:

$$2\,BF_3 + 6\,RMgBr \longrightarrow 2\,BR_3 + 3\,MgBr_2 + 3\,MgF_2$$

Halide displacement reactions between other boron halides and compounds with active hydrogen atoms are quite facile. The first step is often the formation of an adduct, which may be isolated at low temperature, followed by the elimination of the hydrogen halide:

$$BX_3 + 3\,ROH \longrightarrow B(OR)_3 + 3\,HX$$
$$CH_3SH + BCl_3 \xrightarrow{-20\,^\circ C} BCl_3 \cdot CH_3SH$$
$$\xrightarrow[-20\,^\circ C]{\text{above}} CH_3SBCl_2 + HCl$$

In general the reactivity of boron trihalides toward compounds with active hydrogen atoms

increases with decreasing B–X bond energy, in the order $BF_3 < BCl_3 < BBr_3$. Side reactions leading to alkyl halides and boric acid rather than simple halide displacement are more common with the triiodide and sterically hindered alcohols.

1.2.3. Boron Trihalides as Lewis Acids

Boron trifluoride forms adducts with a large number of electron donors including ethers, alcohols, ketones, amines, phosphines, arsines, thiols, and selenides. Those complexes with large electron donor atoms or sterically hindered bases tend to be less stable. Boron trichloride also forms many stable complexes with electron donors, but these are more prone to halide displacement reactions than are the BF_3 adducts. Few stable adducts are known with BBr_3 or BI_3.

1.2.4. Reduction Reactions

Reaction of boron halides with hydrogen, hydrides, or alkali metals often yields boron subhalides or elemental boron. If hydrogen or a hydride is used, boranes may result, e.g., in the following convenient preparation of diborane:

$$6\,LiH + 8\,BF_3 \cdot O(C_2H_5)_2 \longrightarrow B_2H_6 + 6\,LiBF_4 + 8\,(C_2H_5)_2O$$

1.3. Production

Boron Trifluoride. Boron trifluoride was first prepared by the reaction of boric acid and fluorspar (CaF_2) at red heat [12]. Commercially, BF_3 has been produced by the stepwise addition of hydrofluoric acid and sulfuric acid to anhydrous borax (sodium tetraborate):

$$Na_2B_4O_7 + 12\,HF \longrightarrow Na_2O \cdot (BF_3)_4 + 6\,H_2O$$

$$Na_2O \cdot (BF_3)_4 + 2\,H_2SO_4 \longrightarrow 4\,BF_3 + 2\,NaHSO_4 + H_2O$$

Another method involves addition of sulfuric acid and fluorspar and a source of boron, such as anhydrous borax or boric oxide (B_2O_3).

A process was developed in which BF_3 is obtained by the reaction of HF and boric acid, using oleum as a dehydrating agent [13].

$$H_3BO_3 + 3\,HF \longrightarrow BF_3 + 3\,H_2O$$

Boron trifluoride is made commercially in the United States by a proprietary process from boric acid and hydrofluoric acid.

A variety of synthetic routes are available for the production of small quantities of BF_3, including thermal decomposition of diazonium fluoroborate. The diethyl etherate adduct, $BF_3 \cdot O(C_2H_5)_2$ [*109-63-7*], produced by bubbling BF_3 into diethyl ether, provides a convenient source of BF_3 for many synthetic applications.

Boron Trichloride. This compound can be prepared by the reaction of boric oxide, a reducing agent, and chlorine in a melt at high temperatures, for example:

$$B_2O_3 + 3\,C + 3\,Cl_2 \xrightarrow[\Delta]{} 3\,CO + 2\,BCl_3$$

The product BCl_3 is recovered by fractional condensation. Sodium tetraborate $Na_2B_4O_7$ can be used in place of B_2O_3. Molten sodium chloride, formed as a byproduct, settles to the bottom of the reactor [14]. A molten combination of aluminum chloride and an alkali-metal chloride has also been used as a medium for reductive chlorination of borates [15].

Free-radical chlorination of borate esters also yields BCl_3:

$$B(OCH_3)_3 + 9\,Cl_2 \longrightarrow BCl_3 + 3\,COCl_2 + 9\,HCl$$

A modification of this process, in which a free-radical initiator is used, has been reported [16], [17]. A low reaction temperature, 40–90 °C, and the use of an initiator decrease the consumption of Cl_2 and prevent the formation of phosgene, $COCl_2$.

Commercially, boron trichloride is prepared by the reaction of boron carbide with chlorine in a borate melt. This reaction can also be done with dry B_4C in a fluidized-bed reactor using a transition-metal halide as a catalyst [18].

Contamination of BCl_3 with $COCl_2$ from the chlorination of carbon oxides is a serious problem in BCl_3 manufacturing. Because of similar vapor pressure–temperature curves, BCl_3 and $COCl_2$ cannot be separated by fractional distillation. Thermal or photochemical conversion of

$COCl_2$ to CO and Cl_2 followed by fractional distillation has been used to purify BCl_3.

Boron trichloride can be prepared in the laboratory by the reaction of boron trifluoride and aluminum chloride.

Boron Tribromide. This compound can be prepared by the reaction of boric oxide, carbon, and bromine, or from boron carbide and bromine analogous to the chlorine reactions.

Small quantities of BBr_3 can be made by the reaction of boron trifluoride and aluminum tribromide. A five-fold excess of $AlBr_3$ increases the yield of BBr_3.

Boron Triiodide. Boron triiodide can be prepared by the reaction of a borohydride and iodine:

$$3\,MBH_4 + 8\,I_2 \longrightarrow 3\,BI_3 + 3\,MI + 4\,HI + 4\,H_2$$

where M is lithium, sodium, or potassium.

The reaction between sodium borohydride and iodine in dimethylformamide (DMF) results in $BI_3 \cdot 4\,DMF$ [19]. Boron triiodide can also be made by exchange reactions between AlI_3 and BF_3, or between LiI and $LiBH_4$. Contrary to an earlier report, boron triiodide can be prepared from the elements by the reaction of amorphous boron with iodine at 870 °C [20].

1.4. Quality Specifications, Chemical Analysis

Boron trifluoride is available in quantity as a 99 % pure gas. Boron trichloride is typically sold as a 99.9 % pure liquid. Boron tribromide is offered in grades up to 99.9999 % for electronic applications.

Common impurities in BF_3 include air, silicon tetrafluoride, and sulfur dioxide. The major impurities in boron trichloride are phosgene and chlorine. Boron tribromide typically contains traces of bromine.

The boron halides may be analyzed by hydrolysis followed by analysis of B_2O_3 and the halide, or by base titration. The concentration of phosgene ($COCl_2$) in BCl_3 may be determined by infrared spectroscopy. The trifluoride, trichloride, and tribromide may be purified by fractional distillation.

1.5. Sources, Handling, and Transportation

Allied Corp. is the major producer of boron trifluoride. Boron trifluoride complexes with monoethylamine, phenol, and diethyl ether are also available in large quantities from Allied. Complexes of BF_3 with water, dimethylamine, monoethylamine, phosphoric acid, and piperidine are available from Harshaw/Filtrol. Kerr-McGee Corp. is the major producer of BCl_3 and BBr_3. Boron trifluoride and trichloride are available in steel cylinders. Boron tribromide is available in glass bottles. Boron tribromide for use in electronics is supplied by J. C. Schumacher Co. in specially sealed glass vessels equipped with teflon valves. Boron triiodide is available in small quantities from the Ventron Division of Morton-Thiokol Inc.

Boron trifluoride and boron trichloride sold for \$ 6.83/kg (\$ 3.10/lb) and \$ 8.38/kg (\$ 3.80/lb) in bulk in 1984. The 1982 price for BBr_3 was \$ 57/kg (\$ 26/lb) in large quantities from Kerr-McGee.

Boron trifluoride is the largest volume boron halide. The total annual production of BF_3 and its adducts is about 2300 – 4500 t/a. The annual production of BCl_3 is about 225 – 450 t/a. The annual production rate of BBr_3 is significantly less than that of BCl_3.

The boron trihalides are nonflammable. But because they hydrolyze easily, care should be taken to avoid exposure to moisture. The DOT classification for BCl_3 and BBr_3 is corrosive liquid; BF_3 is classified as a nonflammable gas. Equipment for conveying the compounds should be flushed with dry air prior to use. Stainless steel lines and valves are suitable for use with all dry boron halides.

1.6. Uses of Boron Trihalides

Boron Trifluoride. Boron trifluoride is the most widely used boron halide. Most applications take advantage of its strong Lewis acidity. The most important uses are in organic syntheses. Boron trifluoride is commonly used as a catalyst for Friedel-Crafts alkylation reactions. It also is used to catalyze the cleavage of ethers to alcohols, to catalyze esterification reactions,

and in the nitration and sulfonation of aromatic compounds. Many olefin polymerization reactions use BF_3 as an initiator, in conjunction with a proton donor, such as water. Also BF_3 is used to catalyze the isomerization of alkenes and alkanes and in petroleum cracking and desulfurization. Amine complexes of BF_3 are used as epoxy curing agents.

Boron Trichloride. One of the most important uses of BCl_3 is in the preparation of boron fibers (→ Fibers, 5. Synthetic Inorganic). Typically an electrically heated tungsten filament is passed through a chamber containing BCl_3 and hydrogen. The BCl_3 is reduced, and boron is deposited on the filament, producing a stiff, strong boron fiber.

Boron trichloride, like the trifluoride, has been used as a Lewis acid catalyst in organic synthesis in the polymerization of olefins and phosphazines, as well as in catalysis of other organic reactions. Boron trichloride is also used in plasma etching of aluminum and silicon, in semiconductor manufacturing, and as a source of boron for chemical vapor deposition. Steel is boronized by contacting it with a reactive mixture of hydrogen, hydrocarbons, and BCl_3 at high temperatures.

Boron Tribromide. The primary use of boron tribromide is as an initiator for the polymerization of olefins and as a catalyst in other organic reactions. It is also used in the electronics industry as a source of bromine for ion implantation in semiconductors, and for plasma etching in semiconductor device manufacturing.

Boron Triiodide. There are no important commercial uses for boron triiodide.

1.7. Pollution Control, Toxicology, and Occupational Health

Boron halides are not major pollution sources. Fluoride, from the hydrolysis of BF_3, can be precipitated from waste water as CaF_2 by the addition of a calcium salt [21–23]. Aqueous boron (boric acid or borates) can be precipitated by the addition of calcium salts at high pH.

Boron halides are quite toxic and contact with skin or eyes should be avoided. A TLV ceiling limit of 1.0 ppm, 3 mg/m^3 (TWA), has been set for BF_3 by the ACGIH. The MAK values are the same. For BBr_3, the adopted TLVs are 1 ppm, 10 mg/m^3 (TWA); 3 ppm, 30 mg/m^3 (STEL). The LCs in air for BF_3 and BCl_3 in male rats (1 h exposure) are 387 and 2.54 ppm, respectively [24]. These compounds are not known to be carcinogenic.

2. Fluoroboric Acid and Fluoroborates

2.1. Physical and Chemical Properties

In the older literature and in some commercial usage, HBF_4 and its salts are referred to as fluoboric acid and fluoborates. Nomenclature based on fluoroboric and fluoroborates has now become generally accepted in the literature and is used throughout this chapter [29].

The fluoroborate anion, BF_4^-, is essentially the adduct of BF_3 and F^-. The ion is tetrahedral, with B–F bond lengths of about 0.140–0.145 nm compared to a B–F bond length of 0.129 nm in BF_3.

The fluoroborate anion hydrolyzes in water in a stepwise manner to give first hydroxyfluoroborates, then boric acid:

$$BF_4^- + H_2O \longrightarrow (HO)BF_3^- + H^+ + F^-$$
$$(HO)BF_3^- + H_2O \longrightarrow (HO)_2BF_2^- + H^+ + F^-$$
$$(HO)_2BF_2^- + H_2O \longrightarrow (HO)_3BF^- + H^+ + F^-$$
$$(HO)_3BF^- \longrightarrow B(OH)_3 + F^-$$

Concentrated solutions of alkali-metal fluoroborates are stable toward hydrolysis; the anion is more easily hydrolyzed in solutions of transition-metal fluoroborates. Concentrated aqueous solutions of fluoroboric acid, tetrafluoroboric acid, HBF_4 [*16872-11-0*], can be made, but HBF_4 has not been isolated. Solvated species have been crystallized, including $H_3O \cdot BF_4$, $H_5O_2 \cdot BF_4$, and $[H(CH_3OH)_2] \cdot BF_4$ [30]. The term fluoroboric acid, as used commercially, always refers to an aqueous solution of HBF_4.

Many transition-metal fluoroborates are quite soluble in water. Alkali-metal salts are less soluble. Ammonium, sodium, and potassium fluoroborate crystallize as anhydrous salts.

Transition-metal salts all crystallize with various degrees of hydration. Many metal fluoroborates are also soluble in methanol and ethanol. Silver and copper(II) fluoroborate are soluble in diethyl ether and aromatic solvents.

Solid fluoroborate salts decompose upon heating, evolving BF_3. The heat of dissociation increases with cation size for the alkali-metal fluoroborates [31]. The reaction has been used as a convenient source of BF_3 for laboratory applications:

$$NaBF_4 \longrightarrow NaF + BF_3$$

2.2. Production

Fluoroboric acid is usually made by the reaction of hydrofluoric acid and boric acid in water:

$$4\,HF + B(OH)_3 \longrightarrow HBF_4 + 3\,H_2O$$

The reaction is exothermic.

Most of the commonly used fluoroborate salts can be prepared by reacting metal oxides, hydroxides, or carbonates with fluoroboric acid. Ammonium fluoroborate can be made from ammonia and fluoroboric acid. Fluoroborate salts can also be prepared by the reaction of BF_3 with a metal fluoride in a nonaqueous, inert solvent, such as HF, BrF_3, or SO_2.

2.3. Quality Specifications, Chemical Analysis

Fluoroboric acid is available from Harshaw/Filtrol in two grades, Electropure and Fluopure, a lower purity material. Specifications for Electropure fluoroboric acid are given in Table 2.

Table 2. Specifications for Harshaw/Filtrol Electropure fluoroboric acid

Component	Specification	Typical average
HBF_4	48 – 50 %	48.5 %
H_3BO_3	0.5 – 1.5 %	0.75 %
Fe	10 ppm max.	4 ppm
Cu	1 ppm max.	< 1 ppm
Pb	1 ppm max.	< 1 ppm
Zn	1 ppm max.	< 1 ppm
Cl	3 ppm max.	< 3 ppm
SO_4	50 ppm max.	< 50 ppm
Ni	2 ppm max.	< 1 ppm

Solid alkali-metal fluoroborates may contain some hydroxyfluoroborates and boric acid as contaminants. Metal fluoroborate solutions may contain free boric acid or fluoroboric acid as well as trace amounts of metallic impurities.

Fluoroboric acid can be analyzed by hydrolysis, followed by precipitation of fluoride with calcium and titration for the borate. Metal fluoroborates have been analyzed by electrolytic reduction followed by mannitol titration for boric acid [32]. A BF_4^- ion selective electrode is available from Orion. The tetrafluoroborate ion can also be analyzed by ion chromatography [33], [34].

2.4. Sources, Handling, and Transportation

Fluoroboric acid is available from Allied Corp., Harshaw/Filtrol, C.P. Chemicals, Fidelity Chemicals, Harstan, and Ozark-Mahoning. A variety of fluoroborate salts is produced by C.P. Chemicals, Harstan, Allied, Harshaw/Filtrol, and Fidelity Chemicals. Transition-metal fluoroborates are commonly sold as aqueous solutions. They may contain a slight excess of boric acid, added as a stabilizer. Information on commercial fluoroborates is given in Table 3.

Fluoroboric acid and solutions of fluoroborates are corrosive and are shipped in plastic drums or polyethylene pails. Glass vessels should not be used for containing these solutions.

Solutions of fluoroboric acid and fluoroborates are classified as corrosive materials for shipping.

2.5. Uses

The primary use of fluoroboric acid is in the preparation of other fluoroborate salts. Fluoroboric acid is also used in electroplating and in dipping solutions for surface treating of aluminum. It has been recommended as a pickling agent for hot rolled steel [35], and has been patented for use as an etchant for silicon and glass in the electronics industry (→ Electrochemical and Chemical Deposition, Chap. 4.) [36], [37].

Table 3. Commercial fluoroborates

Compound	CAS registry no.	Formula	Commercial form	Price (1984), $/kg
Fluoroboric acid	[*16872-11-0*]	HBF_4	49 % solution	2.01
Alkali-metal salts				
Ammonium	[*13826-83-0*]	NH_4BF_4	crystalline solid	3.73
Potassium	[*14075-53-7*]	KBF_4	crystalline solid	3.13
Sodium	[*13755-29-8*]	$NaBF_4$	solid	3.09
Transition-metal salts				
Antimony(III)	[*14486-20-5*]	$Sb(BF_4)_3$	solution	6.66
Cadmium(II)	>[*144-86-19-2*]	$Cd(BF_4)_2$	50 % solution	5.00
Cobalt(II)	[*26490-63-1*]	$Co(BF_4)_2$	solid	–
Copper(II)	[*38465-60-0*]	$Cu(BF_4)_2$	45 % solution	2.31
Indium(III)	[*27765-48-6*]	$In(BF_4)_3$	solution	–
Iron(II)	[*15283-51-9*]	$Fe(BF_4)_2$	41 % solution	1.06
Lead(II)	[*13814-96-5*]	$Pb(BF_4)_2$	51 % solution	1.87
Nickel(II)	[*14708-14-6*]	$Ni(BF_4)_2$	45 % solution	3.55
Silver(I)	[*14104-20-2*]	$AgBF_4$	powder	–
Tin(II)	[*13814-97-6*]	$Sn(BF_4)_2$	50 % solution	7.69
Zinc(II)	[*13826-88-5*]	$Zn(BF_4)_2$	40 % solution	–

Molten alkali-metal and ammonium fluoroborates are good solvents for metal oxides and are commonly used in fluxes for soldering and brazing.

A mixture of LiF and $NaBF_4$ has been studied as a nuclear reactor coolant [38] and as a solvent for fissionable materials. Mixtures of NH_4BF_4 with nitro compounds are useful as explosives [39].

Alkali metal fluoroborates and fluoroboric acid have also been used as catalysts in organic synthesis and in polymerization reactions.

Lithium fluoroborate is used as an electrolyte in lithium – sulfur batteries.

The fluoroborate anion is similar to perchlorate, ClO_4^-, in its size, shape, and lack of ability to form coordinate bonds with transition metals. Fluoroborates are often used in transition metal chemistry where a noncoordinating anion is required.

The primary use of transition metal fluoroborates is in electroplating. The fluoroborate ion is electrochemically inert and solutions of fluoroborates are highly conductive. Metals plated from fluoroborate solutions include cadmium, copper, indium, iron, lead, nickel, silver, tin, and zinc.

2.6. Pollution Control, Toxicology

Aqueous solutions of fluoroborates can be hydrolyzed and treated with calcium compounds to precipitate calcium fluoride for pollution control [40–42]. Reverse osmosis has also been used to purify waste streams containing potassium fluoroborate [43].

Protective equipment used with hydrofluoric acid should also be used when handling solutions of fluoroboric acid or fluoroborates.

Little information is available in the literature on the toxicity of fluoroborates. Fluoroborate given intravenously to rats depressed levels of L-thyroxine [44], and ammonium fluoroborate was shown to be nontoxic to fresh water minnows at concentrations less than 600 mg/L [45].

3. Boron Subhalides

All of the compounds, B_2X_4, where X is F [*13965-73-6*], Cl [*13701-67-2*], Br [*14355-29-4*], or I [*13703-80-5*], are known. The tetrafluoride is the most stable, but all four compounds decompose at room temperature to BX_3 and other boron halides. The compounds are Lewis diacids and form 1 : 2 complexes with amines and other Lewis bases. Boron tetrachloride, which is the most commonly used of these tetrahalides, can be prepared by reduction of BCl_3 in an electrical discharge apparatus. The most important use of B_2X_4 compounds is in diboration reactions, i.e., the addition of B_2X_4 to unsaturated organic molecules. These reactions are analogous to hydroboration reactions with diborane. Some of the decomposition products of B_2Cl_4 have been characterized. They include B_4Cl_4, B_8Cl_8, and B_9Cl_9.

4. Boron Sulfide

4.1. Physical and Chemical Properties

Boron sulfide [*12007-33-9*], B_2S_3, M_r 117.81, is a colorless compound normally obtained as an amorphous glass. It is extremely difficult to purify and often contains traces of silicon (from glass vessels), oxygen, or sulfur, which may impart a yellow color to the material [46]. The amorphous form does not have a well-defined melting point but begins to sublime at about 300 °C. Some of the physical properties are given in Table 4.

Table 4. Physical properties of B_2S_3

mp (crystalline form), °C	563 [47]
Flow point (amorphous form), °C	310 [46]
bp, °C	≈ 300, sublimes [46]
Density, ϱ, g/cm^3	1.92 [48]
B−S Bond energy, kJ/mol	360 [49]
Heat of fusion, kJ/mol	150 [46]
Heat of vaporization, kJ/mol	252 [50]
Average B−S bond length, nm	0.1808 [48]

An X-ray analysis of crystalline B_2S_3 indicates it is composed of $(BS)_3$ and $(BS)_2$ rings linked through bridging sulfur atoms in a two-dimensional lattice [48].

Boron sulfide reacts with a variety of protonic reagents [51]:

$$B_2S_3 + 6\,H_2O \longrightarrow 2\,B(OH)_3 + 3\,H_2S$$
$$B_2S_3 + 6\,ROH \longrightarrow 2\,B(OR)_3 + 3\,H_2S$$
$$B_2S_3 + 6\,R_2NH \longrightarrow 2\,B(NR_2)_3 + 3\,H_2S$$

The reaction with water is quite violent.

Boron sulfide inflames in chlorine, and is oxidized at high temperature by carbon dioxide or by oxygen [51]. At high temperature it also readily attacks quartz and silicate glass [46]. Boron sulfide reacts with sulfur to give B_8S_{16}, a planar molecule [52]. A variety of other higher molecular mass boron sulfides is also known [53].

Boron sulfide can also act as a sulfidizing agent [54] and can be used to replace a terminal oxygen atom with a terminal sulfur atom in both organic and inorganic systems [55], [56].

4.2. Production

Boron sulfide is difficult to prepare in a pure form. The reaction of boron hydrides or metal borides with sulfur or sulfur compounds yields impure B_2S_3 [46]. Higher purity product is obtained by the reaction of amorphous boron with H_2S or sulfur. Other preparative reactions that have been reported [47], [48] are:

$$3\,FeS + 2\,B \xrightarrow{700\,^\circ C} B_2S_3 + 3\,Fe \text{ [47]}$$
$$Ag_3B_5S_9 \xrightarrow[10\,d]{600-800\,^\circ C} B_2S_3 \text{ [48]}$$

The *recommended route* for the synthesis of pure B_2S_3 is the decomposition of $(XBS)_3$, where X is Cl, Br, or I [46], [51]:

$$BBr_3 \xrightarrow{H_2S} (SBSH)_2 \xrightarrow{BX_3} (XBS)_3 \longrightarrow B_2S_3$$

4.3. Uses

Boron sulfide has been used in organic synthesis to reduce sulfoxides to thiols [57], and to convert ketones to thioketones [55],[58]. The sulfide glasses, $M_2S-B_2S_3$, where M is Li or Na, have electrical conductivities 10^3 times greater than the corresponding oxide glasses [59]. Electrically conducting boron sulfide glasses have also been made incorporating LiI [60] and other glass-forming sulfides [61], [62]. These glasses have potential as electrolytes in batteries or fuel cells.

Boron sulfide is available in research quantities from the Alfa-Ventron Division of Morton-Thiokol (USA).

5. Boranes

5.1. Diborane and Higher Boranes

Introduction. Alfred Stock and co-workers began working on the hydrides of boron in 1912 [63]. From then until 1936, he discovered a series of boron hydrides of the composition B_nH_{n+4} and B_nH_{n+6}, which he named boranes.

Research on boron hydrides was started in the United States by H. I. Schlesinger, who with A. Burg published a new preparation of diborane in 1931 [64]. Impetus was added by

government sponsorship of various military programs to develop high-energy fuels for rockets and aircraft during World War II. Boron fuels (alkyl penta- and decaboranes) created great interest because they possessed much higher heats of combustion than conventional hydrocarbon fuels. Large quantities of boron fuels were manufactured under projects HEF (Olin Matheson Chemical Corp.) and ZIP (Callery Chemical Co.).

Attention has been expanded to other chemical properties of the boranes since 1956, when H. C. Brown discovered hydroboration procedures [65] (1979 Nobel Prize). His work has opened new avenues of research, one of which was to obtain chiral and optically specific compounds required in biological activity.

Progress in borane research was thwarted by inconclusive theories of structure and reactivity until the second half of the century, when W. Lipscomb and co-workers defined the structural and theoretical aspects of the boron hydrides through X-ray diffraction studies [66] (1976 Nobel Prize). This breakthrough in borane chemistry gave new impetus to boron research and to the discovery of the most thermodynamically and kinetically stable class of boranes, the polyhedral anions, carbaboranes, and metalloboranes.

Collectively, boranes are compounds of very complex structure with $B-H^{\mu}-B$ and (open or closed structured) $B-B^{\mu}-B$ tricentered bonds, with H^{μ} equal to linking hydrogen atoms. Explanation of structures and unusual bonding of these compounds has furthered the theory of chemical bonding [67]. Nomenclature of these compounds has been confusing, however, and recommendations to clarify their structures have been made by IUPAC and ACS [68].

5.1.1. Physical and Chemical Properties

The lower boranes are very reactive to oxygen and moisture. Diborane(6), B_2H_6, and air mixtures containing 75 – 98 % diborane detonate in air when sparked, and concentrations over 0.5 vol % can lead to explosions in air or oxygen even without an ignition source. For investigations of oxidation see [69–71]. Pentaborane(9), B_5H_9, a volatile liquid, reacts readily with air and moisture. Solid decaborane(14), $B_{10}H_{14}$, should be handled in an inert atmosphere; exposure should be avoided because of the compound's toxicity (see Table 8). Solutions of $B_{10}H_{14}$ and carbon tetrachloride are explosive and more shock sensitive than nitroglycerine [72]. Some physical properties of the most commercially available boranes are given in Table 5 (see below).

As a Lewis acid, the borane(3), BH_3, group complexes with Lewis bases, analogous to coordinate compounds of the Werner type; the ligands NH_3, NH_2R, and NR_3 are common to the two cases [73]. The Lewis acid BH_3 combines with another borane (Lewis acid) to give the relatively stable borane(6); hence borane groups may be considered as operational "electron-deficient" bases as well as Lewis acids. How the nature of the base or nucleophile affects the cleavage of diborane is controversial and has been discussed [74]. With neutral bases the two modes of cleavage, symmetric or unsymmetric, may occur to give molecular or ionic fragments as shown in Figure 1 (see next page). Generally with large bases or weaker donor atoms symmetric cleavage occurs. Base displacement reactions readily occur and the relative stability of the complexes is:

Group V: P > N
Group VI: S > O
Group V > Group VI

Table 5. Physical properties of boranes

Formula	CAS registry no.	M_r	*mp*, °C	*bp*, °C (101.3 kPa)	$\Delta H°$ fusion, kJ/mol
B_2H_6	[*19287-45-7*]	27.69	−164.9	−92.6	35.5

Figure 1. Cleavage of diborane
∗ L is any ligand. ∗∗ Modes of cleavage.

Lewis bases react with decaborane, without deprotonation, evolving hydrogen with the ligands coordinating at the 6,9 position. This species, $B_{10}H_{12}L_2$, is a key intermediate in the synthesis of the very stable and useful *closo*-boranes, $[B_{10}H_{10}]^{2-}$, and carbaboranes (where carbon is inserted in the 1,2 position of the polyhedron, i.e., 1,2-$C_2B_{10}H_{12}$).

Bridge hydrogens of the boranes are acidic as demonstrated by titration of $B_{10}H_{14}$ and by deuterium exchange [75], [76]. Abstraction of a proton forms hydropolyborate anions, such as $B_5H_8^-$. They are useful intermediates in the formation of higher boranes, heteroboranes, and metalloboranes. These anions, containing a B−B edge bond, can be reacted with diborane to expand the polyhedron [77].

5.1.2. Production

Diborane(6) is available from Callery Chemical Co., Callery, Pennsylvania (USA). The method preferred for the commercial preparation is the addition of boron trifluoride to a stirred solution of sodium borohydride in diethylene glycol dimethyl ether (diglyme):

$$3\ NaBH_4 + 4\ BF_3 \xrightarrow{\text{Diglyme}} 2\ B_2H_6 + 3\ NaBF_4$$

Diborane is shipped either as a compressed gas (ambient) or as a liquid (cylinder over packaged with dry ice). It is packaged as a hazardous material regulated by the DOT [78].

Tetraborane(10), B_4H_{10}, can be obtained by the action of acid on borides [79–81]. It has been prepared from the decomposition of diborane at 120 – 180 °C [82] and under pressure [83]. Tetraborane can also be prepared from the reaction of acid on commercially available $B_3H_8^-$ salts, e.g., NaB_3H_8 [*12429-74-2*].

Pentaborane is obtained by passing diborane through a hot tube. Careful control of temperature, pressure, and flow are required to obtain good yields and avoid further pyrolysis to higher hydrides.

Decaborane can be produced by several procedures, none of which give high yields; all require extensive preparatory time or equipment. It is best produced by the pyrolysis of diborane between 120 – 240 °C. The solids thus produced are removed from the reactor by dissolution and further purified by sublimation.

5.1.3. Uses

Most of the boranes are highly reactive. This property makes them useful and important chemicals, but also necessitates special care in their application.

Diborane serves as a strong but selective reducing agent in organic chemistry. It is an electrophilic reagent and reacts markedly different from the nucleophilic alkali-metal boron and aluminum hydrides. The rates of reduction with diborane were found to decrease in the order: carboxylic acids > olefins > ketones > nitriles > epoxides > esters > acid chlorides [84]. Reductions of several other organic substrates have been studied, for example, oximes [85], perfluorinated olefins [86], diene polymers [87], and organic acid amides [88].

Hydroboration, the addition of diborane or borane to olefins, has found great significance in preparative chemistry [65]. Hydroboration is applicable to multiple bonds between C−C, C−O, C−N, N−N, N−O. Diborane catalyzed by the presence of an ether adds, in an anti-Markovnikov mode, virtually quantitatively to the carbon – carbon double bond of olefins, forming an alkyl borane.

Other important derivatives of diborane are Lewis base adducts, carbonyl adducts, and oxygen-containing products. Further areas of application for diborane are the doping of semiconductor silicon and germanium. Diborane is readily decomposed at high temperature (600 – 700 °C) [89] to give fine-powder, high-purity elemental boron. Copyrolysis of diborane with hydrocarbons yields boron carbide,

and with NH_3 yields boron nitride. These materials, deposited on metal substrates as thin, hard layers, are used in ceramics, tools, and wear-resistant parts. Boron fibers are formed from the decomposition of diborane on substrates and used for light-weight structural components.

The large cross-sectional area of the ^{10}B isotope for neutron capture makes these compounds especially useful in nuclear applications. Borane is also supplied as stable liquid adducts $(CH_3)_2S \cdot BH_3$ [*13292-87-0*] (Callery Chemical Co., Aldrich Chemical Co.), and as a 1 M solution in tetrahydrofuran (THF) [*14044-65-6*] (Aldrich Chemical Co., Ventron Div. of Morton-Thiokol Inc.).

5.2. Amine Boranes

Most amine boranes are white solids, stable to air and moisture. Primary and secondary amine boranes are, however, thermally unstable above 70 °C.

Aliphatic amine boranes are soluble in a variety of protic and nonprotic solvents, in contrast to $NaBH_4$. Hydrolysis is slow under neutral conditions and increases in rate as the pH is lowered. Arylamine boranes are hydrolyzed much more readily.

Production. Preparation may be by reaction of diborane or dimethyl sulfide borane with an amine, or by reacting an ammonium salt of the desired amine with $NaBH_4$ in an ether [90]. The dimethyl sulfide borane route is the most convenient method of preparing small quantities of amine boranes [91].

Both $(CH_3)_2NH \cdot BH_3$ [*74-94-2*] and *tert*-$C_4H_9NH_2 \cdot BH_3$ [*7337-45-3*] are available in up to tonnage quantities, whereas smaller quantities of $(CH_3)_3N \cdot BH_3$ [*75-22-9*], $(C_2H_5)_3N \cdot BH_3$ [*1722-26-5*], $(C_2H_5)_2NH \cdot BH_3$ [*2670-68-0*], pyridine borane [*110-51-0*], and morpholine borane [*4856-95-5*] are commercially available (Callery Chemical Co., Bayer AG).

Uses. The largest quantities of amine boranes are consumed in the electroless plating of various metals, primarily nickel. Dimethylamine borane is the preferred reductant in North America, whereas diethylamine borane is used in Europe. The nickel thus plated by chemical reduction is amorphous and contains varying amounts of boron depending on the bath formulation [92]. This plating mainly provides corrosion protection and high solderability to electrical parts. Amine boranes have also been used to plate copper, gold, palladium, cobalt, and other metals [93].

Amine boranes are finding expanding use as mild reducing agents, comparable to cyanoborohydride in reducing power, but considerably less toxic. Amines of greater base strength give amine boranes of diminished reducing power; for example, $(CH_3)_3N \cdot BH_3$ is a relatively weak reducer, whereas $NH_3 \cdot BH_3$ is a moderately strong reducer.

It has been shown that $NH_3 \cdot BH_3$ and primary and secondary amine boranes are efficient stereoselective reducing agents for aldehydes and ketones in a variety of solvents [94]. Additionally, these reagents selectively reduce aldehydes in the presence of ketones or esters [95], [96].

Chiral amine boranes have been useful in the asymmetric reduction of prochiral ketones. In the presence of BF_3 etherate, borane complexes of sodium salts of amino acids gave enantiomeric excesses up to 62 % [97].

Pyridine borane in acidic media is a versatile and powerful reducing agent. It reduces aldehydes, ketones, oximes, Schiff bases, tosylhydrazines, and aryl alcohols [98].

Polymer-bound amine boranes (Amboranes, Alpha Ventron) have been proposed for the recovery of precious metals. They are effective, if slow, reducing agents for imines, enamines, aldehydes, and ketones [99].

Amine borane analogue of amino acids showed anti-inflammatory activity in rodents [100].

5.3. Borohydrides

Of the borohydrides or hydroboron ions, the most common and most completely studied is the tetrahydromonoborate(1−). The oxidation state of the central atom in the higher hydroboron ions is fractional in ions containing several boron atoms and the charge is listed as a suffix in parentheses [101]. Generally, the borohydrides are highly polarizable [102] and the bonding may

vary from essentially ionic to essentially covalent.

All of the alkali-metal tetrahydroborates have been prepared and are white crystalline solids with markedly different solubilities. Sodium tetrahydroborate(1−) [*16940-66-2*], $NaBH_4$, M_r 37.83, is stable in dry air, reacting slowly with moisture. Hydrolysis is catalyzed by acid, but can be terminated with sufficient sodium hydroxide [103]. Salts of the ions $B_3H_8^-$, $B_{11}H_{14}^-$, $B_{10}H_{10}^{2-}$, and $B_{12}H_{12}^{2-}$ are all white crystalline solids. The latter two salts are extremely stable thermally, especially their halo derivatives $B_{10}X_{10}^{2-}$, $B_{12}X_{12}^{2-}$.

Production. Sodium tetrahydroborate is made by the addition of methyl borate to hydrogenated sodium in mineral oil [104], [105]:

$$4\,Na + 2\,H_2 + B(OCH_3)_3 \xrightarrow[275\,^\circ C]{oil} NaBH_4 + 3\,NaOCH_3$$

Separation of the sodium methoxide from $NaBH_4$ was accomplished by such methods as extraction with amines [106], and extraction with water followed by a counterextraction with a solvent, such as 2-aminopropane [107]. Sodium borohydride is produced commercially by Ventron Div., Morton-Thiokol (USA) [108].

A simple preparation for $B_3H_8^-$, adaptable to large scale, involves the addition of B_2H_6 to $NaBH_4$ in diglyme at 100 °C [109]. Further addition of B_2H_6 to the $B_3H_8^-$ at higher temperature yields $B_{12}H_{12}^{2-}$ [110].

Uses. A concentrated aqueous solution of $NaBH_4$ stabilized by NaOH is used to reduce hydrogen sulfite to dithionite in the bleaching of ground wood pulp [111]. Also, $NaBH_4$ has extensive and important use as a reducing agent in organic synthesis. Other hydroborates can be obtained by reaction with $NaBH_4$ to give different reductive capabilities (e.g., $NaBH_3CN$ [*25895-60-7*]) [112].

Additional applications are extensive, e.g., electroless plating [113], blowing agent for cellular plastics [114], removal of heavy metals from waste streams [115], polymerization catalyst [116], and hydrogen source for fuel cells [117]. The $B_3H_8^-$, $B_{10}H_{10}^{2-}$, and $B_{12}H_{12}^{2-}$ may also find use in the latter application. The quaternary ammonium salt of $B_3H_8^-$ [*33055-82-2*] is used as a fogging agent in photographic film [118]. Chloro derivatives of $B_{10}H_{10}^{2-}$ and $B_{12}H_{12}^{2-}$ lithium salts have been used as battery electrolytes [119]; $B_{12}H_{11}SH^{2-}$ [*12448-23-6*] was useful in a study of neutron-capture therapy in brain tumors [120].

5.4. Carbaboranes

Carbaboranes are boron hydrides with one to four of the polyhedral sites occupied by carbon atoms. The carbon atom, like the cage boron atoms, can bond singly to hydrogen, carbon, etc. The number of known substituted carbaboranes is very large [121], [122] and has grown rapidly.

The largest body of literature is based on 1,2-dicarba-*closo*-dodecaborane(12) [*16872-09-6*], *o*-carborane, 1,2-$C_2B_{10}H_{12}$, M_r 144.23, *mp* 285–287 °C, and its derivatives (for cage numbering system see [121]).

Production. 1,2-Dicarba-*closo*-dodeca-borane(12) is prepared from $B_{10}H_{14}$, a Lewis base, such as dialkyl sulfide, and acetylene [123]. *C*-Substituted derivatives can be readily prepared from substituted acetylenes or from lithio reagents, such as 1,2-Li_2-1,2-$C_2B_{10}H_{10}$ [*22220-85-5*] [121].

Heating 1,2-$C_2B_{10}H_{12}$ under inert conditions at 450–500 °C gives 1,7-$C_2B_{10}H_{12}$; at 600 °C it gives a mixture of 1,7-$C_2B_{10}H_{12}$ and 1,12-$C_2B_{10}H_{12}$ [*20644-12-6*], sometimes called the meta and para isomers, respectively.

There is a large body of literature on the rest of the $C_2B_nH_{n+2}$ family ($n = 3-10$) [124], but the members having $n < 10$ are of little commercial significance.

One boron atom may be removed from 1,2-$C_2B_{10}H_{12}$ and 1,7-$C_2B_{10}H_{12}$ to yield the open-cage species *nido*-7,8-$C_2B_9H_{12}^-$ and *nido*-7,9-$C_2B_9H_{12}^-$, respectively. Further degradation yields *arachno*-boranes (e.g., $C_2B_nH_{n+6}$) as well as nido and closo species [125].

The nido cages have been compared with cyclopentadienide ion as ligands for transition metals. Indeed, a rather large number of transition-metal carbaborane complexes are known [126]. Complexes with two carbaborane cages sandwiching a transition metal are common, e.g., $Co(B_9C_2H_{11})_2^-$, whereas cages containing two

transition metals, usually also bonded to cyclopentadienide, are also known. Some smaller carbaboranes form multidecker complexes with transition-metal cyclopentadienyls [127].

Carbaboranes, like polyhedral boranes, undergo Friedel-Crafts halogenation, although halogenation is complete only for the chlorine derivative [121].

Uses. The early development of carbaborane substitution chemistry was propelled by the search for polymers that would be heat stable at very high temperatures. Polyesters, siloxanes, chains linked with Si, Ge, S, and others were investigated [121].

A short review of structure – property correlations for linear polycarborane – siloxanes has been published [128]. Much of the original work on poly-1,7-carboranylsiloxanes was done at Olin Corp., which formed a company (Dexsil Chemical Corp.) to market the materials under the trade name Dexsil. Early hopes were that markets would grow for high-temperature seals, gaskets, *O*-rings, and coatings. However, costs and therefore prices have remained too high to justify most such uses.

One application that may remain economically viable is the use of poly-1,7-carboranylsiloxanes as stationary phases for high-temperature gas chromatography. For example, Dexsil 300 GC is a low-melting solid that can be used up to 450 °C and even at 500 °C for short times. A bibliography of their use in gas chromatography is available [129].

Carbaboranes have been attached to halo-substituted cyclotriphosphazines. A heat-resistant linear polymer is formed when the monomer is heated [130].

If the residual Cl atoms are replaced with hydrocarbyloxy groups in the polymer, boron atoms can be removed by piperidine to form nido cages, which can complex with transition metals, such as Rh. These polymeric metal complexes might be useful as immobilized catalysts with high temperature stability [131].

A series of rhodacarborane complexes that exhibit high activity as hydrogenation or alkene isomerization catalysts has been developed [132]. One of the most active homogeneous hydrogenation catalysts ever reported is *closo*-1,3-[$\mu(\eta^2$-3-CH_2=$CHCH_2CH_2$)-3*H*-3-$P(C_6H_5)_3$-3,1,2-$RhC_2B_9H_{10}$ [*76166-14-87*], containing a chelating 3-butenyl side chain attached to the carborane cage. Hydrogenation produces a noncoordinating butyl group, freeing up an uncoordinated site on the rhodium [133]. The alkene – metalloborane catalyst may be bound to a suitable polymer for use as a heterogeneous catalyst [134].

Thermal reaction of 1,3-dicyanobenzene in the presence of 1,2-dicarba-*closo*-dodecaborane(12) produced *s*-triazines [135].

1-Alkyl-1,2-dicarba-*closo*-dodecaboranes(12)(especially the *n*-hexyl derivative) have found use in solid aluminum composite propellants as burning rate enhancers [136] based on OH- or CO_2H-terminated polybutadienes. Exceptionally high burning rates have been achieved when part of the NH_4ClO_4 oxidizer was replaced by carboranyl diferrocenylmethyl perchlorate or methyltricarboranylmethyl perchlorate [*61919-09-3*] [137]. A series of nido – closo dicage monoanions exhibited high antifungal activity. The combination of lipophilic *closo*-carboranyl groups with hydrophilic *nido*-dicarbollide anions may lead to the antimicrobial activity [138]. A review covers the physiology of various carbaborane derivatives [139].

Several carbaborane derivatives may find use in boron neutron-capture cancer therapy (BNCT), based on the high cross section of ^{10}B for thermal neutron capture. The products are an α particle and a ^7Li ion with an average kinetic energy of 3.8×10^{-13} J. Use of boranes in BNCT has been reviewed [139, pp. 610 – 631].

p-[1,2-Dicarba-*closo*-[1-^3H]-dodecaborane(12)-2-yl]benzenediazonium chloride [*82187-51-7*] was complexed with goat anti-CEA IgC (carcinoembryonic antigen immunoglobin C), and the antibody lost little immunoreactivity up to five carbaborane cages per molecule [140]. Thus carbaborane-substituted tumor-specific antibodies may be a good method of concentrating ^{10}B in tumors, a goal for many years.

An approach to treatment of hormone-sensitive tumors is to attach carbaborane cages to estradiol or testosterone [141]. Growth of human breast cancer cells was equally stimulated by 17-α-carboranylestradiol [*85197-15-5*], Carbestrol [142].

Carbaborane-substituted polyphosphonates have shown a high affinity for calcified tissues.

They may be useful for BNCT of calcific tumors [143].

6. Organoboranes

6.1. Alkyl- and Arylboranes

Physical Properties. Mono- and dialkylboranes usually associate as dimers through hydrogen bridges (see Fig. 1). However, if the alkyl group is bulky, i.e., sterically hindered, the mono- or dialkylborane can exist in monomeric form, e.g., thexylborane [*3688-24-2*]. The bulkiness of the alkyl group considerably affects the properties of the borane. Compounds containing large hindered groups often are solid products, and as the size of the group decreases, the normal state of the compound goes from solid to liquid to gas. Properties of selected organoboranes are given in Table 6.

Chemical Properties. Generally the organoboranes are very reactive with oxygen and total exclusion is recommended on handling. The low homologues (methyl to butyl) are spontaneously combustible (pyrophoric) in air. Although dilution of the alkylboranes to about 15 wt % in an inert solvent reduces the pyrophoricity, oxidation by air still occurs. The trialkylboranes do not form strong donor-acceptor complexes with ethers, but other stronger Lewis bases form complexes, and stabilization toward oxidation is dependent upon steric factors. The trialkylboranes are insoluble in and unreactive with water. They are not readily protonated by water or alcohols, amines, or mineral acids; however, they are readily protonated by carboxylic acids. They are soluble in and unreactive with aliphatic and aromatic hydrocarbons.

Triarylboranes are generally solid, less sensitive to oxygen, and also unreactive with water.

Triorganoboranes can be stored indefinitely at ambient temperature under an inert atmosphere. Decomposition occurs at elevated temperature: tetraethyldiborane [*12081-54-8*] is one of the pyrolysis products from triethylborane, and butene is observed from tri-*n*-butylborane at 100 °C after an extended period of time. Isomerization and cyclization occur at > 200 °C, giving complex mixtures. Alkylhaloboranes, like the trihalides, react with water, alcohols, and alkoxides, and cleave ethers to yield the corresponding derivatives of boron acids [146].

Production. Two general methods of producing trialkylborane compounds are alkylation and hydroboration. Alkylation of readily accessible boron compounds, borate esters, or preferably boron halides is accomplished with organometallic compounds of Mg (Grignard reagents), Zn, Al, Sn, and alkali metals:

$$3\,RMgX + BF_3 \xrightarrow{(C_2H_5)_2O} R_3B + 3\,MgXF$$
$$3\,R_2Zn + 2\,B(OR)_3 \longrightarrow 2\,R_3B + 3\,Zn(OR)_2$$
$$R_3Al + B(OR)_3 \longrightarrow R_3B + Al(OR)_3$$

where R is alkyl. Aluminum alkyls are least expensive and therefore the preferred alkylating agents in commercial production of trialkylboranes. The exothermic reaction can be controlled at < 100 °C and the product is easily distilled [147]. Grignard reactions are especially useful in producing trimethylborane as well as arylboranes. Triphenylborane has been prepared by reacting finely divided sodium metal with a haloaromatic and a secondary alkyl borate ester [148]; it is made commercially by Du Pont (USA). Hydroboration [66] can be conducted in various ways, i.e., by direct addition of diborane to the olefin at 30–50 °C, or by use of a Lewis base as a reaction medium, with THF

Table 6. Properties of selected organoboranes [144], [145]

Formula	CAS registry no.	*mp*, °C	*bp*, °C (kPa)	Density, g/cm^3 (°C)
$(CH_3)_3B$	[*593-90-8*]	−160	−21.8 (101.3)	0.63 (−100)
$(C_2H_5)_3B$	[*97-94-9*]	− 93	95 (101.3)	0.685 (20)
$(C_4H_9)_3B$	[*122-56-5*]	− 34	170 (29.6)	0.756 (20)
$[(CH_3)_2CHCH_2]_3B$	[*1116-39-8*]	− 88	88 (3.1)	0.731 (30)
$(C_6H_5)_3B$	[*960-71-4*]	142	203 (2.0)	–
$(C_2H_5)_2BCl$	[*5314-83-0*]	− 84.6	78.5 (101.3)	–
$(C_4H_9)_2BCl$	[*1730-69-4*]	–	173 (101.3)	0.879 (20)

and $(CH_3)_2S$ being preferred. Various alkylboranes are commercially available by this method (Callery Chemical Co., Aldrich Chemical Co., Ventron).

As the olefin becomes bulkier, fewer additions can be made. A tetrasubstituted olefin usually forms only the monoalkylborane. Lewis base adducts of the mono- and dichloroboranes yield the mono- and dichloroalkylboranes when reacted with olefins. These can be converted to their respective di- and monoalkylboranes by hydride addition [149]. Mixed trialkylboranes were obtained using this method [150].

Uses. Organoboranes are finding an ever increasing role in organic synthesis. Mono- and dialkylboranes have been used as stereoselective reducing agents, and asymmetric synthesis, hydroborations, and reductions have been accomplished using organoboranes [151]. Such reactions are most significant for their biological application in the pharmaceutical industry, and may mean a small but cost effective use of alkylboranes.

Significant volumes of trialkylboranes are used in catalytic polymerization of ethylene, vinyl derivatives (acetates and halides, acrylic acid, acrylonitrile, and methyl methacrylate) [152–154]. Free radicals are formed during autoxidation of the trialkylborane or during the decomposition of the resulting peroxides [155], [156]. Unique products have also been obtained with copolymers and graft polymers. Water-resistant dental and surgical adhesives having high binding power and being nonirritating to tissue have been developed using alkylborane as a catalyst [157], [158]. The amine complexes of triarylboranes can be used as catalysts for homo- and copolymerization of acrylic monomers.

Several reactions of organoboranes have possible applications in the petroleum industry [159]. Economics remain unfavorable because of high costs of the organoborane and equipment to implement recycle. Amine complexes of the trialkylboranes have been used as additives to increase the cetane rating of diesel fuels. The complexes also inhibit sludge formation in fuel oils.

Triethylborane, because of its ease of oxidation, provides rapid ignition of nonhypergolic fuel in aircraft, and serves as an additive to prevent flameout and increase flame speed.

Lithium and potassium hydride complexes of trialkylboranes are highly reactive and selective reducing agents, and have found small but growing commercial applications.

The tetraarylborates(1−) are used in chemical analysis because of their low solubilities with specific cations (K, Cs, Rb, Ag, Tl). This property can also be used to remove these materials from various chemical waste streams.

The production of organoboron compounds is relatively small compared to other organometallic chemicals. Expensive raw materials and low volume of production tend to keep manufacturing costs high.

6.2. Borinic and Boronic Acids

Borinic and boronic acids are the mixed hydroxyorganoboranes R_2BOH and $RB(OH)_2$, respectively. Two commercially available acids are: phenylboronic acid [*98-80-6*], phenylboric acid, $C_6H_5B(OH)_2$, M_r 121.93, *mp* 217–220 °C; and diphenylborinic acid–ethanolamine complex [*524-95-8*], 2-aminoethyl diphenylborinate, $(C_6H_5)_2BOCH_2CH_2NH_2$, M_r 225.10, *mp* 192–194 °C. Replacement of the organo group by hydroxyl changes the properties of the boranes dramatically. Most of them are stable, water soluble, less susceptible than triorganoboranes to autoxidation, and do not initiate olefin polymerization. Their acidity is dependent on the organo moiety, with the aryl derivatives being the more acidic. The anhydrides of borinic acids are the boroxines, trimeric cyclic $(RBO)_3$ compounds, whereas the anhydrides of the boronic acids are $R_2B{-}O{-}BR_2$.

Production. These acids have been prepared by Grignard synthesis. Borate esters give methyl-substituted acids [160]. Alkyl acids can readily be prepared from hydroboration of olefins using complexes of haloboranes followed by hydrolysis. Rearrangement of triorganoboranes with triorganoborates yields esters, which are susceptible to hydrolysis to the acids.

Uses. The acids are of great interest because they are utilized in the production and reactivity of biologically active compounds. Boronic acids have been prepared in high optical purity for

application in organic synthesis [161]. Specific boronic acids have been found to inhibit the catalyzed hydrolysis of enzymes [162]. Stabilizers are also formed from phenols and arylboronic acids. Benzeneboronic acid derivatives, such as cyclic condensation products with *o*-aminophenol and pyrocatechol, have a sterilizing effect on insects (flies) [163]. Also, compounds of benzeneboronic acid are stimulants for plant root growth. The acids are used in chromatographic columns to enhance separation. They also serve as inhibitors for the autoxidation of fuels and mineral oils.

6.3. Borazines

Borazine [*6569-51-3*], *s*-triazaborane, $B_3N_3H_6$, M_r 80.53, sometimes called inorganic benzene, is a low-boiling liquid (*bp* 55 °C, *mp* −58 °C), consisting of a six-membered ring containing alternating boron and nitrogen atoms, each bonded to a hydrogen atom.

Production. Borazine can be prepared by copyrolysis of $NaBH_4$ and NH_4Cl in a high-boiling glyme [164], by reduction of trichloroborazine [*933-18-6*] [165], or by pyrolysis of ammonia borane in diglyme [166].

A large body of literature exists on the preparation and chemistry of symmetrically and unsymmetrically substituted borazines [167]. *B*-Substituted trihaloborazines, readily prepared from BX_3 and NH_4Cl, react with Grignard reagents to give symmetrical trialkyl- or triarylborazines. Symmetrically substituted *N*-trialkyl- or *N*-triarylborazines are readily prepared from $LiBH_4$ and RNH_3Cl, or by pyrolysis of RNH_2BH_3.

Borazine is thermally stable at 0 °C, but decomposes slowly at ambient temperature. Borazine hydrolyzes slowly, but trihaloborazines hydrolyze quite rapidly. Hydrogen halides form 1 : 3 adducts with borazine, which decompose to trihaloborazines on warming.

Uses. Films that were deposited thermally from borazine vapor were found to be too reactive to be suitable for fabricating masks for X-ray lithography [168]. However, films containing predominately cubic boron nitride, CBN [*10043-11-5*], were deposited using ions extracted from a borazine plasma via an ion beam. Very hard, adherent films were deposited on ceramic, glass, stainless steel, etc. [169]. An obvious practical application is the hardening of tool surfaces to markedly extend their life.

A thermally deposited film of hexagonal BN [*10043-11-5*], from $B_3N_3Cl_6$ [*19087-72-0*] at 900 °C, protected SiO_2 tubes from halide corrosion [170].

A copolymer between 2,4,6-tributylborazine [*7325-06-6*] and an unsaturated *N,N′*-hexamethylenebiscarboxamide was useful for hardening epoxy resins [171]. Trichloroborazine was used as part of a catalyst mix for the polymerization of propene [172].

Flexible BN coatings on copper or copper-base alloys were formed from gaseous 2,4,6-trichloroborazine. The films were stable to 700 °C in air [173].

6.4. Boric Acid Esters

The first boric acid esters were prepared in 1846 by reactions of aliphatic alcohols with boron trichloride [174] and represent the earliest known examples of organoboron compounds. Simple boric acid esters have the formula $B(OR)_3$, where R can be alkyl or aryl; related compounds, such as boroxines, $(ROBO)_3$, as well as boric acid esters of di- and polyfunctional hydroxy compounds can be prepared readily and are included in the general category of boric acid esters. The IUPAC committee on boron chemistry suggested naming simple boric acid esters as trialkoxy- and triaryloxyboranes, and this nomenclature has been adopted by the American Chemical Society [175] and by Chemical Abstracts. However, this system is not normally used in industry or in the scientific literature, where these compounds continue to be referred to as boric acid esters, alkyl (or aryl) borates or orthoborates, trialkyl (or aryl) borates or orthoborates, and (rarely) boron trialkoxides or aryloxides. For example, the most common derivatives are usually referred to as methyl borate, ethyl borate, phenyl borate, etc. Extensive discussions of the chemistry of boric acid esters can be found in [176], [177].

Table 7. Properties of some boric acid esters

Compound	Name	CAS registry no.	*mp*, °C	*bp*, °C (at 101.3 kPa)	d_4^t	n_D^t
$B(OCH_3)_3$	methyl borate	[*121-43-7*]	−29	68.0–68.5	0.920^{20}	1.3548^{25}
$B(OCH_3)_3-CH_3OH$	methyl borate azeotrope	–	–	54.3	0.8804^{25}	1.3472^{25}
$B(OCH_2CH_3)_3$	ethyl borate	[*150-46-9*]	−84.8	117–119	0.859^{26}	1.3723^{25}
$B[OCH(CH_3)_2]_3$	isopropyl borate	[*5419-55-6*]	–	139–140	0.815^{23}	1.3750^{25}

* Phenyl borate has been reported to melt over a wide range of temperatures from 38 to 146 °C

Physical Properties. Boric acid esters range from colorless, low-boiling liquids to high-melting solids. Physical properties of some of the more common materials are given in Table 7. For a more extensive compilation see [176], [178]. Boric acid esters are monomeric compounds generally soluble in organic solvents. They dissolve in water with hydrolysis to boric acid and the corresponding alcohol or phenol.

Chemical Properties. Alkyl boric acid esters from straight-chain alcohols and aryl boric acid esters are stable to relatively high temperatures. Branching in the alcohol chain leads to reduced stability.

Most boric acid esters react readily with water to yield boric acid and the respective alcohol or phenol, and this tendency to react with atmospheric moisture has seriously restricted their general utility. Reactivity toward water can be modified by either steric or electronic effects as shown by the improved hydrolytic stability of compounds, such as tri-*tert*-amyl borate [*22238-22-8*] and triethanolamine borate. Comparative hydrolysis rates have been reported for a number of boric acid esters [179].

Other reactions of boric acid esters include the formation of amine complexes, transesterification, usually by displacement of lower boiling alcohols by higher boiling alcohols or phenols, reactions with organometallic reagents to form alkylboranes, and reactions with metal hydrides to produce boron hydrogen compounds.

Preparation. Boric acid esters have been prepared in the laboratory by a variety of methods, but the standard approach involves the reaction of boric acid with alcohols or phenols:

$$B(OH)_3 + 3\,ROH \rightleftharpoons B(OR)_3 + 3\,H_2O$$

This equilibrium reaction, which favors the hydrolysis products boric acid and ROH, is displaced to the right by using excess alcohol and removing water by azeotropic distillation with hydrocarbon solvents. This procedure is complicated in the case of methyl and ethyl borates by the formation of azeotropes between the alcohols and the boric acid esters. A closely related method in which boric oxide is substituted for boric acid has also been used.

The relatively easy transesterification of boric acid esters results in ready displacement of lower boiling alcohols and the preparation of higher molecular mass alkyl and aryl derivatives.

A number of less practical laboratory procedures for boric acid esters have been reported, starting with boron halides, trisaminoboranes, and other boron-containing compounds.

Production, Economic Aspects. No published data are available on manufacturing processes for boric acid esters or on their annual production rates. Commercial usage is very limited except for the internal production of methyl borate by the Ventron Division of Morton-Thiokol. This ester is a key intermediate in the Ventron process for sodium borohydride. Some additional quantities of methyl borate and its methanol azeotrope are used in welding and brazing applications. Other commercially available boric acid esters include ethyl borate, *n*-propyl borate, isopropyl borate, *n*-butyl borate, and cresyl borate. A number of boric acid esters prepared from butylene and hexylene glycols are also available commercially, as well as methyl and isopropyl boroxines. Probably, all of these compounds are prepared by the standard reactions of boric acid with the appropriate alcohols or phenols.

Prices for the commercially available boric acid esters are relatively high because of their limited usage. At higher production volumes these prices would be reduced significantly. Methyl borate was available in 1985 at ca. $ 3/kg, and the other esters are generally in the range of $ 3 to $ 10/kg.

Uses. Methyl borate is the boric acid ester of greatest commercial interest because it is used internally for the production of sodium borohydride (and diborane). Methyl borate azeotrope is used as a gaseous flux for brazing and welding, particularly in Europe.

Although numerous patents have been issued on the use of boric acid esters as polymer additives, this application apparently has remained small unless there are proprietary uses that have not been disclosed. Application of small quantities of several derivatives as epoxy resin curing agents has continued with little measurable growth. Despite wide patent coverage, boric acid esters have not been used in any quantity for polymer stabilization. In the 1950s and 1960s boric acid esters derived from glycols were used extensively as gasoline additives. A mixture of these glycol derivatives is being manufactured by U.S. Borax & Chemical Corp. under the trade name Biobor JF for the control of microorganisms in fuel systems containing water. This product can be used successfully in jet fuels, diesel fuels, and fuel oil systems that have water contamination.

Borate esters have also been patented for use as flame retardants for cotton batting, modifiers for the oxidation of hydrocarbons, starting materials for the preparation of trialkylboranes, such as triethylborane and triphenylborane, wood preservatives, hydraulic fluids (particularly alkylated glycol borates), and lubricants.

Transportation, Handling. Shipping regulations for boric acid esters vary depending on the nature of the alcohol or phenol that is bound to boron. Lower molecular mass derivatives have very low flash points, and those derived from alcohols containing one to four carbon atoms must be labeled as flammable, and shipped and stored accordingly. Higher molecular mass compounds present no particular difficulty except in specific cases, such as the easily hydrolyzed borates derived from phenols. Boric acid esters in general hydrolyze rapidly and their exposure to the atmosphere should be minimized. Particularly reactive compounds should be transferred and stored in a moisture-free atmosphere of nitrogen or other inert gas.

Shipping in metal cans or drums is normally acceptable except in cases where hydrolysis can lead to a corrosive product, such as a halogenated alcohol.

Toxicology. The published toxicities of the most common boric acid esters vary from acute oral LD_{50} s of ca. 400 mg/kg in rats for aromatic borates to 1200 – 2100 mg/kg for simple aliphatic esters. These toxicities are directly related to the toxicity of the alcohol or phenol produced on hydrolysis.

7. Toxicology and Occupational Health

The toxicology of boron compounds has been reviewed in 1980 [180]. Experimental animal toxicity data, cases of human exposures, industrial

Table 8. Maximum concentrations in the work environment [184], [185]

	CAS	TWA		STEL		MAK	
	registry no.	ppm	mg/m^3	ppm	mg/m^3	ppm	mg/m^3
Diborane(6)	[*19287-45-7*]	0.1	0.1	–	–	0.1	0.1
Pentaborane(9)	[*19624-22-7*]	0.005	0.01	0.015	0.03	0.005	0.01
Decaborane(14)	[*17702-41-9*]	0.05	0.3	0.15	0.9	0.05	0.3

hygiene, and medical treatments are discussed. There are also other readily accessible sources of information [181], [182]. Diborane(6) is primarily a pulmonary irritant [183]; TLVs and MAKs are given in Table 8 [184]. Overexposure causes respiratory tract injury, and secondary infections may follow [186]. Prolonged exposure to low concentrations causes headaches and other central nervous system (CNS) effects [187]. Diborane is a flammable gas and must be handled in a closed system. Pentaborane(9) and decaborane(14) affect the CNS and can have effects that may be delayed for up to 48 h [187]. TLVs have been set (see Table 8) [184]. Pentaborane(9) is a liquid which should be treated as pyrophoric and must be handled in a closed system. Decaborane(14) is a solid but has sufficient vapor pressure at room temperature to make it a hazard by inhalation, as well as by the dermal and oral routes [188].

Animal toxicity testing of amine boranes has shown that they also affect the CNS [189]; however, no TLVs or MAKs have been set for them. Toxicity is affected by the number and kind of substituents and varies from compounds that are highly toxic to those with low toxicity [189], [190].

The few toxicity studies on borohydrides show that they are corrosive to the skin and eyes [191]. When ingested, sodium borohydride produced death from gas embolism in animals.

The lower trialkylboranes have some toxicity to small rodents at nonpyrophoric concentrations in air [180], [192].

Toxicity of carbaboranes depends mainly on the nature of the substituents [180], [193].

1. Introduction

Cereal grains have been the mainstays of human nutrition throughout history [1 – 4]. They are nutritious, palatable, and easy to store. It is easy to picture pre-historic man eating unmodified grains. Because of the hardness of the dried grains and the subsequent difficulty in chewing the grain, it would appear to be a small step to decide to soak the grains before eating them. Crushing the grain after it had been soaked for a time lead directly to production of gruel. Ubiquitous wild yeast and bacteria will inoculate a gruel setting over night. Placing a stiff gruel in hot ashes or on a hot rock results in a solid material with a much different taste than that of the starting gruel.

How the above events unfolded can only be the subject of conjecture as it occurred before recorded history. Evidence suggests that by the end of the Stone Age man was consuming flat baked products. All grains can be used to produce gruels and all gruels can be baked to produce flat unleavened bread. The step to lighter leavened bread required the use of wheat or, to a much lesser extent, rye. This is still true today.

The next step necessary for the production of baked products was the control of the sour dough fermentation and development of baking ovens. The oldest reported ovens were in ancient Babylonia. The ancient Egyptians had modern-looking ovens as early as 2700 B.C. and by 1750 B.C. and were producing bread leavened chemically and with yeast. Evidence suggests that sour dough bread was known in Europe by the late Bronze Age (800 B.C.) and was known throughout the known World by 100 B.C. During the next few centuries there were gradual improvements in oven design. The next large step came with the development of dough-mixing machines in the second half of the 18th century (the industrial revolution). The production of bakers' yeast in the 19th century resulted in a much shorter production schedule and one that could be automated into large plants.

2. Wheat Types and their Uses

Wheat is the most important cereal grain produced and traded in the world for the production of bread and other baked products. Wheat is a member of the grass family of plants. It is cultivated on more area of the earth's surface than any other crop and is man's major source of food. The world wheat production for 2005 is estimated at 626×10^6 t. This is slightly higher than the previous five-year average of 588×10^6 t. It is estimated that nearly two-thirds of the total wheat production is used for food; the remaining one-third is used for seed, feed, and non-food applications. Wheat is grown from as far north as the Arctic Circle in Finland and near the equator in parts of Africa. However, the major production is in the temperate zones. Major areas of production include: the Great Plains of the United States and Canada, Western and Eastern Europe, Russian Federation, Argentina, Australia, China, and the Punjab of India. There are three species of wheat grown commercially *Triticum aestivum* (common wheat), *T. durum* (durum wheat) and *T. compactum* (club wheat).

Wheat can be of either spring, sometimes called summer, or winter habit. Spring wheat is planted in the early spring as soon as the soil starts to warm and is harvested in the late summer. Winter wheat is planted in the fall. Harvest in the United States is in the early summer. In Europe, where the summers are much cooler and wetter, harvest does not occur until late in summer. In general, there is a negative relationship between yield and protein content of the grain. Thus, spring wheat with its lower yield will generally have higher protein content.

Wheats can vary in their hardness, i.e., the force required for crushing the kernels varies. In North America and in certain other parts of the world, the common (*T. aestivum*) wheats are classified as either hard or soft, and the *T. durum* wheats are referred to as durum wheats. In Europe and many other parts of the world, the common wheats are called soft and the durum

wheats are called hard. This has led to considerable confusion. When a European tells an American that they use soft wheat for bread making the American has the wrong idea. However, he or she is no more confused than the European when the American says we make our bread from hard wheat (durum in the mind of the European). The hardness of wheat is under genetic control [6]. Thus, crossing two hard wheats will give progeny that are also hard. Likewise crossing two soft wheats will lead to progeny that are soft. In addition to the genetic effect, the environment also has a major effect upon the hardness of the kernels. The measurement of hardness of wheat is much more difficult than it might appear at first. Wheat kernels have various sizes and shapes. They also have a pronounced crease. Those factors make it difficult to define the geometry of the test piece that is being crushed. Wheat kernel hardness can either be measured on individual kernels or on the bulk sample. An instrument which measures the individual hardness of 300 kernels and gives a distribution of the force required to crush the individual kernels is available. The technique is useful if mixtures of varying hardness are being measured. The most common way of measuring the hardness of a bulk sample is to grind the sample with a burr type mill and sift the resulting meal. Hard wheats will give a much coarser meal than will soft wheats. The reasons for differences in wheat endosperm hardness are not clear. However, major classes of *T. aestivum* and *T. durum* wheat hardness (texture) seem to be attributable to the presence, absence or sequence polymorphism of the proteins puroindolin a and puroindolin b [5].

Wheats also vary in their color. Most wheats are either red or white. The red color comes from a pigment in one layer of the pericarp cells. In white wheats this pigment is missing. Thus, white wheats are not really white but only nonpigmented. Purple and black wheats are known but they appear not to be grown commercially except in parts of China. The absence or presence of the pigmented layer is under genetic control and, thus, plant breeders can readily change the color of the wheat. From a quality standpoint, color is of relatively little importance. It can be important in products that have a very light color, for example, in some cookies, pasta, or wafer products where red bran specs are readily seen. Breakfast food manufacturer's also like white wheats for producing bran products. The bran from white wheat does not brown as readily as that from red wheat and gives more appealing products.

Common (*T. aestivum*) wheats are hexaploid and resulted from the prehistoric combination of three grass species each having 14 chromosomes. Common wheat thus has 42 chromosomes. Wheat then is made up of three genomes called A, B, and D. Durum wheat is tetraploid and, thus, has 28 chromosomes. It has the A and B genomes but not the D one. Since the gene controlling the hardness of common wheats is on the D genome, it is obviously missing in durum wheats. Perhaps as a result the durum wheats are very hard, much harder than the hard common wheats.

The durum (*T. durum*) wheats that are commercially grown are mostly spring wheats. They are white wheats, containing no pigments in the pericarp. Because of the hard translucent texture of the endosperm they appear amber in color and not chalky white such as found with soft wheats. Red durums are known and are used for feed. Winter durums are also known but not grown to any extent. The last species of wheat is the club wheat (*T. compactum*). In general, club wheats are very soft and are used mainly for cookie and cake flours in North America.

Figure 1. Illustration of wheat hardness and wheat protein content in relation to baked product type.

Wheat is used in countless food products. They include, for example, fermented (leavened) breads, bread specialties, cookies, crackers, cakes, pastries, breakfast cereals, pasta, noodles, and starch/gluten [7 – 10]. The overall use of wheat in relation to wheat hardness and wheat protein content is illustrated in Figure 1. Apart from product and process requirements (wheat

quality or suitability), the use of wheat is determined by factors such as availability, price, contracts and relationships with a supplier (wheat producer, trader, miller), geographic location of the wheat user and the supplier, and regulations (e.g., tariffs) that control the use of specific wheats. For the production of bioethanol from wheat starch see → Cereals, Cereal Products.

3. Wheat Breeding and Biotechnology

The primary efforts of cereal breeding are directed towards (1) increase in grain yield, (2) assembling resistance or tolerance to fungi, bacteria, insects, viruses etc, and (3) improvement of grain quality attributes (e.g., bread making potential) [11 – 13].

3.1. Traditional Breeding

Common wheat is a complicated cereal. It has 42 pairs of chromosomes compared to 14 for maize or rye. This also means it has three sets of genes for each function in the plant. However, all three of the genes may not be active. This complexity makes it difficult to obtain any desired function by conventional breeding. A good example of this is the production of waxy wheat (a wheat in which the starch is composed of amylopectin only with essentially no amylose) [14]. There are three genes controlling the production of amylose. To obtain a waxy variety all three of these genes must be null (not active). The probability of this occurring by chance is very small. It was only when the gene products (proteins) were identified that crosses between lines containing the various mutant genes resulted in waxy wheat.

3.2. Biotechnology

Rapid developments in plant biotechnology have led to the ability to transform or insert new DNA into plants [15 – 20]. Early products of genetic engineering technologies include plants with improved disease protection such as enhanced insect resistance and improved herbicide tolerance. As the world population continues to grow at a rapid rate the problem of producing sufficient food becomes more severe. To meet this challenge, a sustainable advancement in food production must be developed. Plant biotechnology, appears to be an answer to obtaining the sustainable increase in food production.

Indeed it can increase harvestable yield and improve quality of end-products. Specific quality targets of genetic engineered wheat have included the modification of gluten protein fractions, especially the high molecular weight glutenin subunits of wheat glutenin for improved bread making quality [21]. The starch content and structure could be modified, for example, to optimize the noodle-making quality of wheat flour or to extend the shelf life of baked products [22, 23]. Moreover, the nutritional value of wheat may be improved by altering the amino acid profile, e.g., by increasing the essential amino acid lysine. However, it seems likely it may take several years before new wheat improved through biotechnology is commercially available to wheat growers, millers, and food processors.

Consumer acceptance of foods obtained through biotechnology remains a very important issue [24]. An area where wheat improvement through biotechnology, such as wheat of increased starch content, may become more rapidly acceptable, is in the use as a raw material for bioethanol production.

4. Milling of Wheat

The wheat kernel is composed of three main morphological parts: the endosperm comprising starch and storage proteins (ca. 82 %), the bran (ca. 15.5 %) rich in dietary fiber, B vitamins, minerals and metabolizing proteins, and the germ (ca. 2.5 %) which is relatively high in oil. The first objective of milling is to separate these anatomical parts of the wheat kernel as cleanly as possible. This separation is achieved, for the most part, in the break system of the mill. The next objective is to transform the endosperm into materials of smaller particle size, i.e., flours. This is accomplished by the reduction system. The flour used for the production of baked products is essentially the endosperm of the wheat that is reduced to flour composed of a

range of particles, from very small (< 1 μm) up to about 200 μm. Soft wheat (North American terminology) produces a flour with much smaller average particle size than hard wheat (≈40 μm vs. 75 μm, same terminology). In hard wheat, the protein and starch tend to remain together in the flour and cannot be separated without additional grinding to reduce the particle size. As a result of milling cereals can be further processed into more palatable and desirable food. Milling, however, may also decrease the nutritional value by the removal of vitamins, minerals, and dietary fiber present in bran and germ. In recent years there has been a trend towards using whole wheat flours and meals comprising all parts of the wheat kernel for the production of highly nutritional baked products.

Flour Types. Many different flours are produced by the milling operation, one from each grinding step. Flour extraction rates are used to compare yields of flour and are expressed as a percentage of the production of milled products. Flour yields typically vary from 72 % for white flour to 100 % for whole-meal flour. Curves of ash and/or protein extraction (Fig. 2) are useful in determining the maximum yield that can be obtained and still meet the ash and protein specifications of the flour. A composite of all the flours produced by the mill is *straight grade flour*. Depending upon the details of the process it represents about 72 % of the total products. The flour produced at the head (first grinding steps) of the reduction system is *patent flour*.The term short patent is used for flour with the lowest ash content and represents about 45 % of the total products. This flour comes mainly from the center of the wheat kernel. A long patent flour may be up to 65 % of the total products. The term *cut-off flour* is used for the 20 % between the short and long patents. The 7 % between the long patent and the straight-grade flour is *low-grade flour* (also denoted as clear flour). This flour, which comes from the tail end (last grinding steps) of the break and reduction systems, has high ash and dark color. Another product from the mill is millfeed, i.e., bran and shorts; bran represents about 11 % of total products and shorts about 16 %. Germ can be an additional product, usually recovered at about 1.0 %. Developments in milling engineering such as improved process performance, complete process automation and optimization of product control have made flour milling a highly efficient and cost-effective operation [25].

Figure 2. Curves of ash extraction (●–●) and protein extraction (o–o) for a commercial wheat flour mill.

5. Wheat Flour

5.1. Flour Constituents

Wheat flour constituents, specifically starch, proteins, lipids and nonstarch polysaccharides have been extensively studied [7, 8, 26 – 30].

5.1.1. Starch (→ Starch)

Starch is the most abundant component in wheat flour. The level varies but will average nearly 70 % on a dry weight basis. In all cereal grains the plants excess energy is stored as starch. The molecular composition and structure of starch has been examined in relation to starch properties [31 – 35]. Starch occurs only in the endosperm of the seed as small microscopic particles or granules. In wheat, the granules are predominately of two size ranges, i.e., large lenticular (lens shaped) and smaller spherical granules. The large granules average about 25 μm in the large dimension and about 10 μm in the other dimension. The smaller spherical granules average about 10 μm in diameter. The starch granules are tightly packed (density about 1.6 g/L) and partially crystalline. In excess water they absorb about 30 % of their weight and swell about 5 %.

The starch granules are composed of two classes of starch polymers: amylose and amylopectin. Amylose makes up about 25 % of the starch, the remaining 75 % is amylopectin. Amylose is a mostly linear polymer of anhydroglucose units linked α-1 $\rightarrow$ 4. In wheat the amylose polymer is composed of about 1000 to 2000 anhydroglucose units (degree of polymerization, DP 1000 to 2000) and has a molecular mass of about 160 000 to about 320 000. There is a small level ($<$ 1 %) of branching through α-1 $\rightarrow$ 6 bonds. Although amylose is slightly branched, it appears to act like a truly linear polymer.

Amylopectin molecules are very large (DP typically over 600 000) and highly branched polymers. Amylopectin is also predominately composed of α-1 $\rightarrow$ 4 bonds with typically about 5 % α-1 $\rightarrow$ 6 bonds as the branching points. The amylopectin molecules are responsible for the crystallinity in the granule. The crystallites are very small being about 50 $\times$ 200 nm.

Within the granule both the amylose and amylopectin appear to be ordered at right angles to the surface of the granule. This ordering gives the granule the property of birefringence.

When starch is heated in excess water at about 55 °C the crystallites start to melt, the granule swell, and the birefringence is lost over about a 7 °C temperature range (gelatinization). However, the loss of birefringence in individual granules occurs over a much smaller temperature range, showing that gelatinization is a granule per granule event. Gelatinization is essential in most baked products [31, 36 – 43]. The amylose content and the amylopectin branch chain-length distributions predominantly affect the gelatinization and pasting/gelation properties of the starch [44 – 46].

In processing of most baked products the water is limiting. In limited water systems, the temperature at which the starch granules start to melt remains the same, as long as the starch contains more than 30 % water. However, the temperature range over which the crystallites melt becomes much wider [47]. Thus, it is possible that the crystallites are not completely melted and birefringence is not completely lost even at 100 °C. Thus, starch occurs as two phases (soluble polymers and remnants of granules) in most baked products. The ratio of soluble polymers to remnants of granules depends on the water content of the system. Also important is the level of sugars in food systems. High levels of sugars will increase the melting point of the starch crystallites, thereby controlling the gelatinization temperature of starch [48, 49].

Upon cooling and storage, reassociation of the starch chains occurs [40, 50 – 58]. In this context, the term retrogradation is frequently used. It refers to the starch "going back" to its initial crystallinity. In the ungelatinized starch amylopectin is partially crystalline, and upon cooling and storing gelatinized starch both amylose and amylopectin show crystallinity, thus one should only refer to amylopectin crystallization as retrogradation and refer to amylose crystallization as such. The minimum chain length for chain association involving double helix formation and crystallization is estimated to be DP 10. By reducing the chain length through partial β-amylolysis, the retrogradation of amylopectin can be inhibited [59]. The retrogradation of starch is also affected by the presence of sugars, salt and lipids [49, 60 – 65].

Damaged Starch. Starch damage occurs as a result of roller milling when the starch granules are subjected to some shear. Such shear can disrupt the crystallites within the starch granule. As a result of crystallite disruption the starch granules will swell in water at room temperature [31, 66] and will be readily hydrolyzed by α-amylase.

The amount of shear that the granule is subjected to depends on a number of factors. The most important is probably the hardness of the wheat kernel. The harder the wheat the more shear is encountered during milling and, therefore, the more damaged starch is produced. There are both advantages and disadvantages of producing damaged starch during milling. In the case of hard wheat that is being milled into bread flour the damaged starch is an advantage. It increases the water absorption of the flour and, thus, gives a higher yield of dough. More dough is directly related to more bread. Thus, from the same amount of flour the baker obtains a higher amount of baked product.

In bread making the damaged starch swells and starts to solubilize during dough mixing. Starch swelling and solubilization potentially together with starch–gluten interactions increase the strength of the dough. Its greater strength makes it more difficult for the dough to be ex-

panded by the gases produced during fermentation. Therefore, the damaged starch that was beneficial at mixing, to increase water absorption, is detrimental at the end of fermentation. Addition of α-amylase, either as malt or amylase originating from microorganisms, is common at the mill. It has been suggested that amylase is added to produce sugars for the yeast. However, this does not appear logical as a large excess of sugar is added in many bread making formulas. The real reason these enzymes are added is to degrade the damaged starch, which is a readily accessible substrate for amylases. The destruction of the damaged starch is accompanied with a decrease in dough strength and allows the dough to expand much easier during proofing and baking. The result is the increased baked product volume found with amylase supplementation.

In many products traditionally made from soft wheat flours, such as most cookies, damaged starch is a strong detrimental factor. For cookies to spread in the oven during baking, the flour must be very low in damaged starch.

5.1.2. Protein

The protein content of wheat varies over a rather wide range (6 to 18 %) depending on both environmental and genetic factors. In general, as the protein content of wheat increases the starch content will decline. Wheat flour generally contains 1 % less protein than the wheat it is milled form. Thus, to produce a flour of 12 % protein wheat grains of about 13 % protein must be used as starting material. According to the classical Osborne fractionation procedure, cereal grain proteins can be classified into four groups on the basis of their extraction and solubility in a series of solvents: water (albumins), dilute aqueous salt solutions (globulins), alcohol–water mixtures (prolamins) and dilute acids or alkalis (glutelins) [67, 68]. In wheat flour about 15 % of the protein is soluble in water or aqueous salt solutions (albumins or globulins) and the remaining 85 % is storage protein (prolamins and glutelins). The storage proteins in wheat are forming the gluten [69]. Hence, wheat gluten is made up of two classes of proteins, prolamins called gliadin and glutelins called glutenin. It is the gluten protein that is largely responsible for wheat flour producing the viscoelastic dough that retains gas during fermentation resulting in the leavened loaf of bread [70 – 79]. Although there is some variation, in general, the gliadin makes up about 52 % of the gluten and the glutenin the remaining 48 %. Both of these two classes are complicated mixtures of individual proteins.

The *gliadin proteins* are relatively small molecules with an average molecular mass of about 44 000. More than 50 individual proteins have been identified in gliadin, although only 30 or so have been found in any one wheat line. The gliadin proteins consist of single polypeptide chains and, thus, all disulfide bonds would be internal (i.e., intermolecular disulfide bonding). Whereas a mixture of hydrated gliadin is viscous, sticky, and has little elastic properties, hydrated glutenin has strong elastic properties. The *glutenin proteins* are much larger in size than gliadins with an average molecular mass reported to be about 3×10^6. Some of the larger glutenin molecules have been reported to be as large as 20×10^6. The proteins are multichained and consist of many subunits. There are both low molecular mass and high molecular mass subunits. The molecular mass of the former varies from 30 000 to 60 000 and that of the latter from about 65 000 to 90 000.The subunits are linked together by disulfide bonds. Since the repeating unit in the interior of the subunits contains essentially no sulfur-containing amino acids, the disulfide bonds both intra- and intermolecular occur at the ends of the subunits. Apparently only one intramolecular bond exists between any two subunits in dough. Thus, glutenin is polymerized but not crosslinked. It appears that glutenin becomes crosslinked during baking and determines together with the embedded starch the rheological properties of bread crumb [80].

The amino acid composition of gluten at least in part explains its properties. The most prominent amino acid in gluten is glutamine, which makes up about 35 % of the total gluten. Glutamine in the polypeptide chain does not take on a charge, is quite hydrophilic, and easily forms hydrogen bonds. The second most prominent amino acid is proline (14 %). Proline contains a pyrrolidine ring structure and, thus produces a kink in the protein chain. This keeps the protein from forming a helix or similar structure. The level of hydrophobic amino acids in gluten is about 34 %. Only about 28 % hydrophobic

groups can be buried in the center of the protein, thus some of the hydrophobic groups are on the outside of the molecule and allow hydrophobic interactions. The low levels of positively charged amino acids (resulting from the high levels of glutamine and proline) and the absence of negatively charged amino acids result in a protein with a very low charge density. This means the polymers are only slightly mutually repelled and thus can readily interact with each other.

5.1.3. Lipids

Wheat, like all cereal grains, is low in fat or lipid material (ca. 2.0 %). The lipids are not uniformly distributed throughout the kernel. The germ contains the highest level of lipids (ca. 28 %) and the endosperm the lowest (ca. 1.5 %). The lipids in the endosperm occur in small lipid bodies. Flour lipids are a complicated mixture of compounds [81 – 83]. Of the 1.5 % lipids found in flour about one-half are nonpolar lipids (triacyl glycerides, fatty acids, sterols and their esters) and the other half are strongly polar (phospholipids and glycolipids). The polar lipids have strong surfactant properties and play a functional role in the production of baked products [84 – 86].

5.1.4. Nonstarch Polysaccharides (NSP)

The NSP in wheat flour make up the endosperm cell walls. In wheat flour apparently three classes of compounds occur: arabinoxylans, β-glucans with different linkage point, and a glycoprotein with the carbohydrate moiety being an arabinogalactan. All these compounds are dietary fiber constituents. A wide variation in the sizes and chemical structures is found within each of the classes [87 – 94]. While in older literature, the main NSP determining wheat functionality are referred to as pentosans, they are now more commonly and more correctly referred to as arabinoxylans.

Both water-extractable and water unextractable arabinoxylans are found in cereal grains. Water-extractable arabinoxylans are present in about equal levels (typically 0.5 %) in endosperm and bran. The content of unextractable arabinoxylans is much higher in the bran than in the endosperm. Therefore, whereas the level of water-extractable arabinoxylans is relatively independent of the flour extraction rate (ca. 0.5 %), the level of unextractable arabinoxylans in the milled product increases with the rate of flour extraction (ca. 2.0–8 % in milled products) [95]. The water-extractable arabinoxylans impart viscosity to dough, and their water-unextractable counterpart have a high water holding capacity.

Both the water-unextractable [96] and the water-extractable arabinoxylans [97] have been shown to interact with gluten [98]. The water-extractable arabinoxylans stabilize protein foams [92], affect gas retention and undergo oxidative gelation [99 – 102]. The gelation may be an important strengthening mechanism for dough during fermentation [103] The role of arabinoxylans and endoxylanases in bread making is reviewed in [104].

5.1.5. Ash

Typical wheat grains have an ash (mineral) content that ranges from 1.5 to 2.0 %. However, the ash is not distributed uniformly in the grain. The inner endosperm has a relatively low ash content (0.3 %), whereas the bran is higher in ash and may contain as much as 6 %. Thus, the ash content is a convenient and sensitive assay for the presence of bran in flour, as its determination is relatively simple and reproducible. However, wheats vary in the level of ash natively found in the endosperm and, thus, small variations in ash content do not necessarily imply the presence of different concentrations of bran in flours. In general, the ash itself does not affect flour properties, and, thus, it can be argued that the ash content alone has no meaning. However, high ash content indicates the presence of bran in the flour and bran contains compounds that generally are detrimental to bread making performance.

5.2. Chemical Flour Treatments

Flour may receive a number of treatments at the mill. Bleaching is very common in some countries. For bread and all-purpose flours, the most common bleaching agent is dibenzoyl peroxide, which is added as a dry powder and whitens flour

over a two-day period. It only bleaches flour pigments and has no effect on the baking properties. In countries where it is allowed, like the USA, cake flour is treated with chlorine gas. The gas destroys (bleaches) the pigments and gives very white flour. It also strongly affects the flour's functional properties.

Application of chlorine is detrimental to bread flours but beneficial to cake flours [105]. High-ratio cakes (cakes that contain more sugar than flour) cannot be made without treatment with chlorine gas (see Section 16.6.2). In countries where chlorine bleaching is not allowed, no high ratio cakes are produced. Chlorine reacts with almost all flour constituents thereby affecting their functional properties. The rate of reaction is quite rapid with flour and much slower with starch. However, fractionation and reconstitution studies have shown that the reaction with the starch is responsible for the improvement in baking properties. The amount of chlorine gas used is critical. When chlorine reacts with organic material, hydrochloric acid is usually produced. Thus, the pH of the flour is, generally, a good measure of the extent of reaction and therefore of the amount of chlorine added. Generally, an end pH of 4.7–4.9 is desired for most high-ratio cakes. The actual effect of chlorine appears to be its reaction with the starch to give a modified (oxidized) starch, which can swell to a greater extent than untreated starch. This gives a more viscous batter at the same temperature than with unoxidized flour. The increased viscosity of the batter keeps the cake from collapsing in the oven and, to some extent, after it is removed from the oven. Thus, with cake flours chlorine is both bleach and improving agent. Mills in the UK have produced special cake and biscuit flours from special low protein wheat varieties that are chlorinated to give a pH 4.5–5.5. However, chlorination is no longer allowed under EC rules and a substitute for chlorination has yet to be identified [106].

Bread flour also undergoes aging or maturing and concomitant improvement in baking performance with storage [107, 108]. The presumption has been made that aging is an oxidative process. If flour is stored long enough after milling, it slowly bleaches, supposedly because of air oxidation. Interestingly, high ratio cakes can be produced from nontreated cake flour if it is stored for about eight months. Reports suggest that also other mechanisms are involved in the aging of wheat and wheat flour. For example, the break down of the lipid bodies in the endosperm has been related to the aging phenomenon [109, 110]. In an attempt to speed up the aging process a number of oxidizing agents are added at the mill (azodicarbonamide, acetone peroxide, chlorine dioxide, and potassium bromate). These oxidants improve the bread-making potential of the flour, but do not replace aging.

6. Evaluation of Flours

Flour is the most important ingredient in essentially all baked goods. It is the flour that determines the rheological properties of both doughs and batters. Different kinds of baked goods require flours with different properties [111]. For example, flour that is good for bread production may not be satisfactory for producing cookies. The commercial value of wheat flour depends on a number of factors. The quantity and quality of protein, the ash content, color, moisture content, and level of enzyme activity are the most important factors. Flours for the production of yeast leavened products (bread, rolls, etc.) are characterized by relatively high protein contents (> 10.5 %), high water absorption, and moderate levels of enzyme activity. The flours should produce doughs with a good balance of elastic and viscous properties. For the production of chemically leavened products (cookies, cakes, crackers, etc.) wheat flours with low ash, relatively low protein content (8–10 %), and low contents of damaged starch are preferred [112].

There are many methods to evaluate flour quality [113 – 116]. In addition, a number of rapid methods mostly related to near-infrared reflectance (NIR) are becoming more popular [117, 118]. In the next sections evaluation techniques are discussed that are commonly used in the production of baked goods.

6.1. Physical Dough Tests

A number of dough tests are used in an attempt to predict the performance of wheat flours [119 – 121]. Unfortunately none of the tests is successful in making those predictions because

Figure 3. A mixograph curve showing the stages of flour hydration, dough development, and dough breakdown.

difference in flour quality manifests itself during baking. For example, if bread doughs made from flours of different baking quality are all proofed to the same height, they still give large differences in loaf volume after baking. Cookie doughs all cut with the same size cutter will spread to different diameters, and cake batter of the same weight will give different size cakes. Although physical dough tests may fail in predicting final baking performance, they can give useful information related to the processing behavior of flours.

6.1.1. Mixing Curves

Two machines that measure the mixing properties of flour-water doughs are the farinograph [122] and the mixograph [123]. Both machines are torque measuring devices. As flour and water are mixed the dough develops and offers more resistance to being mixed up to a point, beyond which the resistance decreases.

The *farinograph* has two sigma shaped mixing blades that run at a differential (one at 90 rpm and the other at 60 rpm). The mixing action is relatively gentle and is characterized as a kneading action. The mixing bowl is temperature controlled. The procedure for the farinograph calls for centering the farinograph curve (plot of torque vs. time) on an arbitrary 500 Brabender Units (BU) line. To do this, the amount of water in the dough is altered. From the farinograph curve important data are obtained. The curve provides the mixing time (time to peak resistance), the amount of water needed to center the curve on the 500 BU line (water absorption), and the tolerance to overmixing (stability). One problem with the farinograph is that some flours will give a false hydration peak (see Section 7.1) that is often mistaken for the mixing peak. The hydration peak is often more dominant than the mixing peak and with computer analyzed curves it is often taken as the mixing peak. In general, with North American flours farinograph mixing peaks of 3 min or less should be questioned.

The *mixograph* has a much more severe mixing action and, as a result, the peaks are easier to identify. The mixing action is a pulling stretching action instead of kneading. The mixograph allows the determination of the optimum water addition to a flour from the shape of the mixograph curve (Fig. 3). The curve height is related to the flour protein content. The mixing time (time to peak) and mixing tolerance (rate of curve decline after the peak) can be obtained from the curve. A wider tail of the mixograph curve indicates a better tolerance to abuse such as overmixing or overproofing the dough.

In general, strong flours in either instrument will have relatively long mixing times, with good stability, and wider curve widths. The mixing instruments will easily identify flour with good or poor strength and good or poor mixing tolerance. Perhaps the best use of the mixing curves is to check for flour consistency. If the same flour is to be delivered each day and the mixing curve changes it is reason to be concerned.

6.1.2. Flour Strength

Two instrument used to measure flour strength are the extensograph [124] and the alveograph [125]. For the *extensograph* dough is mixed in the farinograph, rounded, and formed into a log shape. The ends of the log are clamped into a holder and after a suitable relaxation time, the holder and dough are placed in the machine and a hook stretches the dough until it fails. The resulting curve gives a measure of the dough strength (curve height) and extensibility (curve length). A good dough will have a balance of strength and extensibility. More fundamental rheological measurements are also being used to measure flour strength [126 – 128].

The *alveograph* has its own mixer that mixes the dough and extrudes a dough sheet. The alveograph forces air under the sheet of dough to blow a dough bubble. The bubble is expanded until it fails and collapses. From the curve (a plot of pressure vs. time) the work used to blow the bubble can be calculated. More work is related to stronger flours.

6.2. α-Amylase Activity

The endogenous enzyme α-amylase is the most important enzyme in regard to bread production since it markedly influences baked product quality [129]. Three instruments are used to essentially measure the α-amylase activity of flours, i.e., the amylograph, the Rapid Visco Analyser, and the falling number apparatus. All three heat a flour–water slurry and measure the consistency/viscosity of the resulting slurry. As the level of α-amylase activity increases, starch is increasingly degraded during heating and a lower consistency/viscosity of the flour–water slurry is obtained.

7. Dough Formation

Production of bread products containing wheat flour begins by mixing flour, water, and various other ingredients to form a dough [130]. When wheat flour and water are mixed in various proportions, they form everything from a slurry when water is in large excess ($\geq 60\,\%$ water on a flour basis), to a dry but slightly cohesive powder when flour is in large excess ($< 35\,\%$ water). At intermediate water levels, the more liquid systems are described as batters, while at about 40–60 % water, the flour–water mixture is more like a sticky mess. However, when such a system is continuously stirred or mixed, remarkable changes occur. The system appears to become less wet and sticky, and a dough with cohesive and viscoelastic properties is formed. In a bread making dough the different flour constituents vary in their water uptake capacity. In a dough system starch (granular and damaged) takes up about 46 % of the water, protein about 32 %, and the arabinoxylans about 22 % [131].

7.1. Underlying Mechanisms of Dough Formation

Flour particles are highly hygroscopic and quickly absorb water. When water is added to the flour, the surfaces of the particles rapidly hydrate because water is in large excess compared to the surface area of the particles. Microscopy studies have shown that upon wetting of flour particles hydrated protein strands are formed at the air–flour–water interface due to surface tension forces [132 – 134, 269]. The strands quickly interact with each other to form physical crosslinks between flour particles.

In the absence of mixing, the only driving force for the water to move from the surface to the center of the flour particle is diffusion, which is slow. Mixing provides an additional mechanism by removing the hydrated surface of the particles and exposing new surfaces on flour particles for interaction with water. As more and more of the free water is used to hydrate the protein and starch, the resistance of the system to extension increases progressively and the height of the mixing curve gradually develops to a peak (Fig. 3). At this stage no intact flour particles are present and continuous protein films with adhering starch granules form a homogenous mixture (dough; Fig. 4). When the dough shows its maximum resistance to extension, it is said to be developed. All the flour particles are now hydrated. Particles from hard wheat flour are dense and water penetrates the particles only slowly whereas particles from soft wheat flour are less dense, smaller, and contain voids

that allow a more rapid moisture uptake. Since dough development is essentially a result of complete hydration of the flour particles and formation of a viscoelastic protein network, doughs from hard wheat flours need longer mixing times than doughs from soft wheat flours. The kinetics of dough development are also affected by the flour protein content. In the mixograph, low protein flours ($< 12\,\%$) require longer mixing times simply because they contain less protein. A flour protein content above 12 % does not affect mixing time. The overall positive relationship between wheat hardness and protein content has already been described (see Chap. 2). A dough that has been mixed to a peak can be referred, for example, as mixed dough, a dough with minimum mobility, or an optimally mixed dough. All of these imply that an end point has been reached, the point to which a dough should be mixed for producing a loaf of bread.

Figure 4. Scanning electron micrograph of a lyophilized mixed dough.

7.2. Role of Proteins in Dough Formation

A dough made from wheat flour is viscoelastic, it exhibits both viscous flow and rubber-like elastic recovery. The various rheological techniques used to follow the bread-making process are described in [136]. Flour protein content and quality are the major factors accounting for the viscoelastic properties of dough and thus dough mixing properties and bread making performance [70 – 73, 75 – 77, 79, 130, 131, 137, 138]. In general, flours with higher levels of protein ($> 12\,\%$) provide stronger doughs with higher elasticity, higher resistance to overmixing, and higher bread making potential. The weight-average molecular mass of the polymeric fraction (glutenin) appears to be particularly important [139].

The composition, structure, molecular size distribution, and aggregative behavior of gliadin [140, 141] and glutenin that together form the gluten mass determine the quality of the endosperm storage proteins. With respect to protein composition, scores have been assigned to the high molecular mass glutenin subunits to rank them in order of their effects on bread making quality [142]. The scores rank the subunits in order of their effects on gluten strength. The mechanism by which certain high molecular mass subunits confer to dough elasticity and bread making properties has been suggested to be related to their structural conformation. The repetitive domains of high molecular mass subunits have a β-helical conformation that may be intrinsically elastic, capable of expansion and contraction in response to stress, and therefore be of significance in the formation of gluten elasticity. It has also been suggested that the size of the glutenin protein may be responsible for its elastic properties [143]. Quantitative effects such as the level and ratio of high and low molecular mass glutenin subunits will also be superimposed on the intrinsic potentials.

In specific subunits the possibility of formation of intrachain disulfide bonds exists. The position and orientations of cysteine residues within the high molecular mass subunits capable of creating intramolecular disulfide bonds affect the generation of a high molecular mass disulfide-bonded polymeric glutenin structure [144 – 148]. This structure is a key factor determining dough strength and elasticity. A hierarchical arrangement of high and low molecular mass glutenin subunits has been proposed in relation to their proposed intrinsic contributions to dough strength [149]. This arrangement is based on the potential of a subunit to form branched polymers and the length of the repeating sequence domain. Branched polymers

and longer repeating sequence domains lead to stronger doughs.

A polymer science model has been proposed for the development of a continuous protein structure in a dough system. The model involves shear-thinning (i.e., slippage of polypeptide chains against one another), and crosslinks and/or entanglements between large glutenin polymers that are constantly breaking and reforming [79, 150]. This allows the polymers to relax after being stressed and thus, to lose their strain. A gluten–water dough has a smaller elastic modulus than a flour–water dough. It appears, therefore, that starch acts as a filler in the gluten polymer. Filled polymers generally have a larger elastic modulus than their unfilled counterparts. This situation is similar to using carbon black as a filler in the rubber for tires.

In general, dough development that is reflected by an increase in dough consistency and a peak at optimum development is followed by a dough breakdown, i.e., a decrease in dough consistency (Fig. 3). Various types of crosslinks such as sulfhydryl–disulfide interchange reactions, noncovalent hydrogen bonds between glutamine side chains, hydrophobic interactions, and chain entanglements affect the rheological dough properties. The decrease in dough consistency upon overmixing, i.e., dough weakening, is accompanied by a breaking down of the large macropolymer glutenin structure, possibly due to the rupture of disulfide bonds and loss of high molecular mass glutenin subunits [151, 152]. Chemical reducing agents such as cysteine, dithiothreitol, sodium bisulfite, and related compounds are quite effective in weakening the dough and shortening mixing time by breaking disulfide bonds. Flour contains the reducing agent glutathione [153]. In contrast, oxidation increases the strength of the dough [154] and the addition of oxidizing agents to a partially reduced dough restores the original dough strength. This treatment is accompanied by a return to the original glutenin molecular mass distribution and thus, provides evidence of the importance of sulfhydryl–disulfide interchange reactions in dough formation. The reaction of oxidizing agents such as iodate and of *N*-ethylmaleimide (NEMI) in dough appears to proceed via blocking of accessible and reactive thiol (SH) groups. This leads to an inhibition of sulfhydryl–disulfide interchange reactions and subsequently to a stabilization of aggregated wheat proteins [131, 155]. Bakers have taken practical advantage of these disulfide interchange reactions during dough processing. By adding minute quantities of reducing substances such as cysteine, dough can be developed much faster at lower mixing speeds, i.e., lower energy input. Such a developed dough is extremely fragile and, where allowed, is stabilized by addition of a slow-acting oxidizing agent such as potassium bromate.

Wheat flour doughs mixed in a nitrogen atmosphere or in the absence of the water-soluble flour fraction do not decrease in dough consistency as a result of overmixing. This observation implies that oxidative reactions mediated by water soluble compounds are involved in the dough breakdown mechanism. Addition of fumaric acid and related compounds to the water-soluble flour fraction reduce mixing time and also greatly increases the rate of dough breakdown [156]. Certain α, β-unsaturated carbonyl compounds such as fumaric, maleic, or ferulic acids have effects on overmixing similar to those of the sulfhydryl blocking reagent *N*-ethylmaleimide. The effect of the activated double-bond compounds on dough breakdown during overmixing can be reversed by lipoxygenase present in enzyme-active soy flour or by free radical scavengers [157]. The pH of the dough also effects mixing time, with lower pH giving a shorter mixing time and higher pH (up to pH 10) giving longer times [158]. This might be explained as an effect upon the charge of the proteins. The effect of low pH can be overcome by addition of salt (presumably by charge shielding). If a dough is mixed to optimum, allowed to relax and then mixed again it will redevelop and the resistance to extension will be restored to its original value. This implies that reversible and/or noncovalent molecular bondings are involved. Direct evidence for the presence of hydrogen bonds in gluten can be inferred from mixing experiments with heavy water (D_2O). Hydrophobic interactions can be related to the high level (30 %) of nonpolar amino acid residues in gluten. The very low charge density of gluten proteins also facilitates chain interactions.

Research is focusing on the interactions between flour constituents, specifically between the different gluten proteins themselves and the non-

protein flour components starch, lipids and arabinoxylans [29, 159].

7.3. Thermodynamic View of Dough Mixing

The phase behavior of biopolymer mixtures and excluded volume effects of macromolecules are critical factors influencing the functionality of dough [160]. During the mixing of flour and water, albumins, globulins, water-soluble starch, and arabinoxylans form a liquid aqueous phase. This is immiscible with the gluten phase. At first, bread dough contains two continuous phases: a gluten thixotropic gel phase and a liquid phase. Mechanical treatment greatly affects the structural–property relationship of doughs by establishing equilibrium between the coexisting phases: transformation of the continuous liquid protein–polysaccharide phase into the dispersed phase and orientation of the polypeptide chains of the gluten phase.

7.4. Aeration of Dough during Mixing

Incorporation of air during dough mixing is necessary to obtain a baked loaf of good volume, structure, and texture. As dough becomes cohesive, it starts to incorporate air and, thus, decreases in density. The small air bubbles created in the dough phase during mixing provide the nucleation sites to which the CO_2 produced by the yeast diffuses during fermentation. Without these nuclei the grain of the final bread would be very coarse with only a few large cells, because yeast is unable to create new gas cells. The viscoelastic texture of the dough is able to retain the CO_2 produced during proofing without rupturing. The total number of bubbles per cubic centimeter dough generated during mixing depends on the mixing conditions. With laboratory scale mixers operating under atmospheric pressure about 5,000–10,000 bubbles with a diameter of about 50–100 μm are incorporated into a dough [161].

Some doughs, as practiced in the Chorleywood bread making process (see Section 9.4), are mixed under vacuum. At first glance, this would appear to be detrimental to its quality. However, the vacuum is not complete. High vacuum cannot exist because dough contains water. The partial vacuum is beneficial for the baked product texture. Mixing under reduced pressure increases the size of existing bubbles and makes them easier to subdivide. The result is a larger number of bubbles which leads to a finer crumb grain.

8. Role of Bread Ingredients [162]

The minimum formula for bread is flour, yeast, salt, and water. If any one of these ingredients is missing, the product is not bread. Other ingredients that are often found in the formula are fat, sugar, milk or so-called milk replacers, oxidants, various enzyme preparations (including malted grain), surfactants, and additives to protect against molds. Each of the components in the formula performs a specific function in producing the finished loaf [7, 8, 163, 164]. The flour, of course, is the major component and is responsible for the structure of the bread.

Yeast. (baker's yeast, *Saccharomyces cerevisiae*) (→ Yeasts) is one of the fundamental ingredients; its major role is to convert fermentable carbohydrates into carbon dioxide and ethanol. The gases that result from that conversion provide the lift that produces a light, or leavened, loaf of bread. In addition to its gas production, the yeast has a marked effect on the rheological properties of dough. Furthermore, yeast fermentation affects texture and flavor characteristics of finished baked products.

Fat/Shortening. Fat has several functions in bread making [165]. In dough making, fat acts as a plasticizer. Thus, if the level of fat in the dough is increased, the amount of water must be reduced and vice versa to maintain an equal dough consistency. Fat increases the volume of the bread. The increase in volume is significant, usually about 10%. In bread that is to be stored for any significant period of time after baking, fat is a desirable ingredient due to its antistaling properties. Bread containing fat in the formula stays soft and more palatable for a longer period of time than does bread prepared without fat.

Sugar is added to the formula as a source of fermentable carbohydrate for the yeast, and if used in sufficient levels provides a slightly sweet taste to the bread. With the proper enzymes present in the dough, sufficient sugar is produced from the flour to maintain fermentation and added sugar is not necessary for gas production. However, under most production conditions, added sugar is used for fermentation. Most Americans will state, when asked, that they do not prefer sweet bread. However, if they are given a series of breads to taste and instructions to rank the breads according to flavor, their rankings will generally follow the raise in sugar level. This probably explains why the level of sugar in U.S. bread continues to increase. In other countries sugar is mainly added to the formula to induce yeast fermentation and to enhance the color of the crust.

Milk or milk solids were a common ingredient in U.S. bread in the recent past. The nutritional advantages of milk are well known. It also had widespread consumer appeal and, because the United States was producing a large excess of milk, it was a relatively cheap ingredient. The latter situation has now changed drastically, and milk is an expensive ingredient. Therefore, it is hardly used anymore. More common are milk replacers such as soy–whey mixtures. Bread for toasting, in general, contains higher levels of milk powder preparations to enhance browning reactions and thus color development during toasting.

Oxidants. The chemical oxidants that are added to the bread formula affect dough rheology and baked product quality [166]. Oxidants such as ascorbic acid [167 – 169], potassium bromate [170, 171], azodicarbonamide, and calcium peroxide, at ppm levels, improve dough strength and result in bread with better loaf volume and texture [154]. Several oxidants (potassium iodate and azodicarbonamide, for example), are fast-acting and are effective during mixing. Potassium bromate, on the other hand, has essentially no effect during mixing but affects dough rheology during fermentation and in the early stages of baking. At least part of the time-dependent effect of potassium bromate may be attributed to the change in dough pH during fermentation; potassium bromate reacts faster at lower pH. Ascorbic acid has both a rapid and a time-dependent reaction on dough rheology. The type and level of oxidants that can be used in bread varies from country to country. In the EU questions have been raised on the value on chemical flour treatments and use of additives. For example, most European countries do not allow the use of bromate for bread flour. However, the functionality of bromate is very complex and the baking industry is facing a challenge in replacing bromate [170].

Surfactants. Bread that must remain soft for a number of days usually contains a surfactant in addition to enzymes (amylases) [172]. The most common compounds for this usage are α-monoacyl glycerols, more commonly (but less correctly) referred to as monoglycerides; a common level of usage is 0.5 % based on the flour weight. Other surfactants are used as dough strengtheners. These are helpful in allowing the dough to withstand the mechanical stress of the bakery's processing lines. Examples of this type of surfactant are, e.g., sodium stearoyl lactylate (SSL), ethoxylated monoglycerides (EMG), and diacetyl tartaric acid esters of mono- and diglycerides (DATEM). They also are used at about 0.5 % of the flour weight.

Enzymes. There is a worldwide trend away from chemical additives in food processing. As a part of this trend, bakers are turning to enzymes as an alternative to chemicals [173 – 175]. Of course, enzymes have been used in baking throughout history. However, the use of enzymes as formula ingredients is relatively new. Often, enzymes have synergistic effects when used in combinations. These effects can be exploited to improve both, processing performance and end-product quality. One of the major advantages of enzymes is that they are considered as processing aids. They act during dough/batter preparation and in the early stages of baking before they are denatured and inactivated. As such, the enzymes need not to appear on the product label. However, some heat-stable enzymes may survive the baking process. If they fulfill a function in the final product, they need to be declared.

α-Amylase. The most popular enzyme added to baking formulas is α-amylase. Too much α-amylase activity result in a poor loaf with a sticky crumb. Too little α-amylase activity results in a

smaller loaf with a course crumb texture. Sound wheats are low in α-amylase. Flours produced from such wheats produce bread with a harsh crumb. To correct this problem, malted barley or malted wheat flour is added, usually at about 0.25 % of the flour weight. This treatment improves loaf volume and reduces the rough texture of the crumb. The proper treatment level can be determined by the amylograph, Rapid Visco Analyser, or falling number tests (see Section 6.2). In very lean formulas with no added sugar the α-amylase together with the endogenous β-amylase produces maltose that can be used for fermentation. If sugar is added to the formula, yeast does not utilize maltose. An important role of added α-amylase is to destroy damaged starch (see Section 5.1.1). Damaged starch has the advantage of increasing water absorption during mixing. However, it is detrimental later in the baking system. Its removal facilitates obtaining a loaf of good volume and texture. Another role of α-amylase that might be linked to the α-amylase related volume and texture improvements, is as an anti-staling aid, keeping bread from firming during storage [50, 176]. Apart from the action on damaged starch, the action of the α-amylase on regular starch is in a time window after the starch has gelatinized (ca. 65 °C) but before the enzyme is denatured. α-Amylase produces dextrins that remain in the final product as the natively present β-amylase which is more sensitive to heat, is no longer active. These formed dextrins may well interfere with the firming of bread.

Xylanases. Other enzymes that are finding more use in baking are xylanases that degrade wheat arabinoxylans [177]. Much progress has been made in understanding xylanase functionality. An important breakthrough was the finding that some xylanases preferentially solubilize water-unextractable arabinoxylans, while others preferentially hydrolyze the water-extractable components [104, 178, 179]. In addition, in the 1990s, it was found that wheat flour contains proteins which can inhibit xylanase enzymes [180 – 183]. In the particular case of bread making, the ideal xylanase is one which preferentially solubilizes water-unextractable arabinoxylan, leaves the water-extractable component intact, and is not inhibited [184]. In a dough system, xylanases appear to improve the rheological properties. This may be explained by the degradation of arabinoxylans that can interfere with the development of a continuous gluten network [175]. Appropriate xylanases are particularly useful in high fiber content breads. In a batter system, depending on their specific action, xylanases can decrease or increase the viscosity of the batter.

Lipoxygenase has several beneficial effects during baking [185, 186]. Lipoxygenase, usually from enzyme active soy or pea flour, has a strong bleaching action. In addition, the lipoxygenase action results in improved mixing tolerance, a strengthening of the dough, and increased loaf volume. Oxygen or hydrogen peroxide produced by lipoxygenase and other oxidative enzymes may play a role in redox reactions of proteins and arabinoxylans during mixing [187].

Glucose oxidase has been used to produce stronger dough. Glucose oxidase produces hydrogen peroxide that appears to be the active agent. This enzyme has been partially successful in replacing certain chemical oxidants in the bread making formula.

Transglutaminase, a protein crosslinking enzyme, has also been suggested to increase or maintain bread volume when other ingredients are substituted or reduced during dough preparation [188, 189].

Proteolytic Enzymes. Various proteolytic enzyme preparations are used by bakers, generally to weaken bucky (too elastic) doughs. Proteolytic enzymes can be divided into exo- and endo-acting types. The endo-enzymes affect dough rheology while the exo-enzymes do not. One problem with the action of endoproteolytic enzymes is that the activity continues as long as the dough phase lasts. This leads to disaster if there is down time. Under such conditions the dough will turn into a sticky mess that cannot be recovered. Proteolytic enzymes are also used in the preparation of batters (e.g., for wafer baking) to avoid gluten protein aggregation (lump formation) and to reduce batter viscosity. These modifications facilitate batter mixing, pumping and batter depositing on the baking plates. The effect of proteolytic enzymes can be attributed to the hydrolysis and subsequent molecular mass reduction of the wheat glutenin polypeptides [190].

Lipase has only been recently introduced into bread making. Beneficial effects include an increase in bread volume, a more uniform crumb

structure and improved softness during storage [175, 191]. It has been suggested that one of the mechanisms of action of lipase in bread making is related to the increase in gluten strength.

Salt/Water. Salt is generally used at levels of about 1–2 % based on flour weight. Salt appears to have two major functions. First is taste; bread made with no salt is quite tasteless. The second is to affect the dough's rheological properties. Salt makes dough stronger, presumably by shielding charges on the dough proteins. The last fundamental ingredient is water, which acts as plasticizer, solvent, and reaction medium.

Other Ingredients. A large number of other ingredients are found in bread formulations. Most, if not all, of these are added to affect the sensory attributes of the resultant bread and not for any technological functional effects. These items include such nongrain ingredients as eggs, honey, syrups, fruits (often dried), nuts, and various spices. Grain other than wheat can be used individually or in combination to add diversity, flavor, and eventually nutritional benefits by blending with wheat flour [192]. Nongrain plant materials (often fibers) are also used occasionally. In many parts of the world wheat flour is enriched for nutritional reasons. In the USA, since 1940, all enriched "family" flour and baker's bread flour have been required to be enriched with the vitamins thiamin, riboflavin, and niacin and with iron. The purpose is to replace part of the vitamins and minerals lost as a result of milling. In 1998, the addition of folic acid was made mandatory for enriched flours in the USA. All UK flours used for bread production must contain at least 0.24 mg of vitamin B, 1.6 mg of nicotinic acid, and 1.65 mg of iron per 100 g of flour. Lower extraction flours are also enriched with calcium carbonate.

9. Bread and Dough Making Processes

There are a large number of processes used to make dough and bread [7, 8, 193 – 196]. In this chapter only the most important ones will be covered.

9.1. Straight Dough

In a straight dough process all the formula ingredients are added together at the start and the mixture is mixed into optimally developed dough. The dough is then allowed to ferment. The fermentation time may vary but generally would be 2–3 h. After fermentation the dough is divided into loaf sized pieces of dough, rounded into a ball, given an intermediate proof time of 10–20 min (which allows the dough to relax), and then molded and panned. The dough cylinders are then allowed to proof for about 1 h before going to the oven. Bread produced by a straight dough procedure is strong, chewy, and tends to have an open grain. The straight dough procedure has a strong time dependence. If a large dough quantity is mixed, the bread produced from the start and end of the dough (perhaps 30 min of elapsed time) will be noticeably different in properties.

9.2. Sponge and Dough

In the sponge and dough process a sponge is prepared from part of the flour (ca. 65 %), part of the water, and the yeast. The sponge is only mixed enough to have a uniform mixture and then allowed to ferment for 3–4 h. After fermentation, the sponge is brought back to the mixer and mixed with the rest of the formula ingredients. At this stage the dough is mixed to optimum development. After mixing the dough is given a floor time (15–20 min) to allow it to relax. It is then processed as described for the straight dough (Section 9.1). The sponge and dough procedure requires more time, more space, and more personnel than the straight dough procedure. In general, it produces bread with a soft and uniform grain. The process is very tolerant, particularly to time. Thus, large batches can be processed with relatively little variation in bread quality. It is also generally believed to give a better bread flavor than the straight dough process.

9.3. Liquid Preferments

Preferments have become increasing popular in the last few years. The use of preferments saves

labor costs, space, and processing time. Preferments consist of water, yeast, sugar, inorganic salts, and flour. The ratio of water to flour is maintained so that the preferment is a pumpable, liquid mixture. Preferments precede dough fermentation and thus, they can be viewed as simply a more liquid sponge that is then combined with other formula ingredients to give a dough. In this sense, preferments are used in place of the sponge. Control of pH is important in preferments. The pH should be maintained between 4.5 and 5.2. The preferment is buffered by the flour, salts, and often milk powder. With no buffer, the pH of a nonflour brew will drop to about 2.5. An advantage of the preferment is that it can be chilled and held for 24 h without loss of activity. Of course, the quantities of flour and water must be adjusted to maintain the original formula. A single preferment can be used not only for bread but also for rolls, snack crackers, and sweet goods such as doughnuts.

9.4. No-Time Processes

These systems really do not require no time. What the term no time refers to is the amount of fermentation time. Several systems have been developed. The continuous system in the USA, the Chorleywood process in the U.K., and the Brimec process in Australia, to name a few. The latter two systems are still widely used in their respective countries. The continuous system in the United States is no longer widely used, although it once accounted for as much as 40 % of U.S. bread production. The *U.S. continuous system* generally used a preferment that was mixed with the other ingredients and developed with a high speed developer under pressure. The dough was then extruded directly into bread pans, proofed and baked. The bread produced had an extremely uniform grain and a very soft texture. Consumers in the U.S., however, appeared to view the bread produced as inferior and sales dropped even though the bread was priced below other bread on the market.

The *Chorleywood process* employs no preferment. It uses a high speed Tweedy mixer and develops the dough under a partial vacuum. The *Brimec process* also uses no preferment and a special mixer developed for this process. The mixer operates at a pressure of 150 kPa and the dough is extruded directly into the baking pan. All short time systems require high levels of oxidants. Commonly used oxidants in the systems are potassium iodate, potassium bromate, and ascorbic acid.

9.5. Sour Dough

Utilization of sour dough is an old-time leavening method in bread making. During sour dough fermentation a typical microflora develops that includes lactic acid bacteria (lactobacilli) and yeasts [197]. The yeasts are generally responsible for the leavening action via carbon dioxide production and for flavor precursor formation. Lactic acid bacteria lower the pH by producing lactic and acetic acid. A typical ratio is about 20 % acetic and the remainder lactic acid. The acidity protects against spoilage by inhibiting mold growth. The growth of rope bacteria is increasingly inhibited as the pH drops below 6.0 and the acids formed preserve the dough. The desired pH of the dough is in the range of 4.0 to 4.6. However, the pH must not become too low, because below about pH 3.7, putrefaction bacteria take over, developing bad odors. Generally this is not a problem, as flour is a relatively good buffer. In addition, lactic acid bacteria produce enzymes (α-amylase, phytase and proteolytic enzymes) that form low molecular mass carbohydrates, peptides, and amino acids that can act as flavor precursors.

For the production of rye bread an acidification is required. The acidity affects the swelling properties of rye flour constituents (proteins, arabinoxylans), controls the enzyme activity in the dough and improves the bread making performance (i.e., improved crumb grain, elasticity, slicing properties, flavor and taste perception, crumb/crust color, and shelf life). Compared to wheat bread rye bread prepared with sour dough has a denser loaf with lower volume, sour-aromatic taste and prolonged shelf life.

The sour dough process is a very complex biological system. Factors affecting this system include process variables such as fermentation temperature and time, and ingredient parameters such as flour type, flour ash content, media sources (availability of carbon, nitrogen-sources, vitamins), pH, water concentration and the presence of antimicrobial compounds. These

parameters affect the multiplication of lactobacilli and yeast, the amounts of acids formed, gas (CO_2, O_2) and ethanol concentrations, the proteolytic activity of lactobacilli, and thereby, the organoleptic properties of the baked product such as taste, flavor, texture, and crumb color.

Sour dough production traditionally includes three stages of fermentation: a fresh sour, a basic sour and a full sour (final dough for breadbaking). To initiate sour dough fermentation and to prepare the fresh sour, a spontaneous sour (spontaneously fermented flour-water mixture), a portion of an already developed, old sour dough or a commercial starter culture derived from natural sour dough fermentations can be used. As dough becomes old, the yeast is inactivted, as the pH is low. At the lower pH, bacteria are still quite active. With time, the food available for the organisms becomes limited; however, as new flour is added and the "starter" is fed or rebuilt, the bacteria become more predominant. In general, the gas-producing ability of sour-dough organisms is lower than that of commercial yeast. Consequently proof time of sour dough bread is often long, of the order of several hours. Various sour dough processes (multi-, two, single stage varying from 2 h up to 24 h) were designed to increase the growth of yeast and lactic acid bacteria to give the final sour dough (full sour) proper acidity (especially the lactic acid/acetic acid ratio) and dough consistency. Often, baker's yeast (*Saccharomyces cerevisiae*) is added to accelerate the leavening process. The use of organic acids (dough acidifiers) including lactic, acetic, tartaric, and citric acids alone or in combination with other additives such as sour dough concentrates can replace sour dough in single-stage processes or partly replace it in multistage processes. Apart from the usual batch process, technologies for continuous preparation of sour doughs have been developed [198]. A comprehensive documentation on sour dough technology, fermentation/microbiology and biochemistry is given in [199].

9.6. Frozen Dough

Frozen dough has gained popularity since the 1970s [200]. Frozen dough usage has been most successful for small goods, puff pastry, Danish, and croissants. Also successful have been bread systems where good control of both the temperature and time of frozen dough storage is attained. The temperature in the freezer should be kept constant and the freezing time as short as possible. Frozen doughs sold in the supermarket have been much less successful primarily because neither time nor temperature are fully controlled.

The deterioration of the baking quality of the dough that has been subjected to prolonged frozen storage has been mainly attributed to two factors: loss of yeast viability and dough strength. The reduction in yeast viability during frozen storage results in a loss of gassing power, longer proof times and, ultimately, reduced loaf volumes. In addition, reducing compounds such as glutathion released from the dead yeast cells cause depolymerization of gluten proteins, which may also be detrimental to dough rheology. The loss of dough strength during freezing has also been attributed to the physical disruption of the gas cell wall structure in the dough by ice crystal formation [201 – 204], which affects gas retention properties of the dough and final bread quality. Freezing and thawing or just variation in the storage temperature, even if it remains below freezing, is also detrimental to the quality (rheology) of frozen dough.

The baking performance of frozen dough can be optimized to a great extent through the use of appropriate formulations and processing conditions [200 – 202, 205, 206]. Standard practice for frozen dough production is to keep the dough cold, and the fermentation time as short as possible, increase the yeast level, and keep the time between freezing and usage as short as possible. Flour quality has also been implicated as a determinant of frozen dough quality [207]. Adhering to those guidelines will produce consistent bread from frozen dough.

There appears to be a trend away from frozen dough and toward par-baked, (i.e., partially baked) products as a process to give the consumer "fresh baked" products without going to the bakery.

10. Gas Production and Retention

10.1. Leavening Mechanisms

Leavening with gases is designed to control specific process requirements (e.g. batter and dough rheology, product density and volume) and to manufacture products with desired eating characteristics such as a light product texture and tender bite. As leavening gases are used: carbon dioxide, water and/or ethanol vapor, ammonia, and air. Leavening starts with the incorporation of air into the dough or batter during mixing to form nuclei of gas cells that will expand during baking. Air is therefore present and used in all baked products. The expansion of the initial gas cells can be achieved by the use of chemical aerating agents and/or yeast. Water is also present in all baked products and in all cases the evaporation of water in the dough or batter plays a role in the expansion process. However, mostly its leavening effect is quite limited because water has a relatively high boiling point. Water vapor is an effective leavener only when the product is heated at a very fast rate due to the rapid increase of water vapor pressure, as done in saltine cracker or wafer production. Yeast fermentation as biological leavening process via carbon dioxide and ethanol production is the major leavener for bread but is only rarely used in soft wheat products. Small amounts of yeast maybe used in some pretzel formulas. Most, if not all, soft wheat products are chemically leavened, that means, carbon dioxide is produced by chemical reactions of bicarbonate or carbonate with acids. The rheological effect of yeast is generally not desirable in soft wheat products. In soft wheat products, sodium and ammonium bicarbonates are the most common sources of carbon dioxide.

10.2. Fermentation and Gas Production by Yeast (→ Yeasts)

Yeast is a living organism that is inactive during storage. The inactivity is caused either by drying, in the case of active dry yeast, or by low temperature, in the case of compressed, crumbled, or cream yeast. Yeast, as it is produced commercially, is always contaminated with bacteria, mainly lactobacilli. These are quite important in saltine crackers and perhaps in some sour dough breads but do not appear to be important in regular bread making processes.

When yeast is incorporated into a dough, conditions are suitable for it to become active. Yeast is a versatile organism; it can ferment under either aerobic or anaerobic conditions [208]. The growth of yeast and the early stages of brewing are a aerobic processes, whereas bread fermentation is an anaerobic process. Thus, little growth of yeast occurs during dough fermentation. The yeast and bacteria rapidly consume the oxygen in dough as fermentation starts. Thereafter, the fermentation is anaerobic unless oxygen is added to the system (e.g., by remixing). The process of anaerobic fermentation of carbohydrates by yeast to the end products, ethanol and carbon dioxide, is summarized below:

$$C_6H_{12}O_6 + \text{yeast} \rightarrow 2\,CH_3CH_2OH + 2\,CO_2$$

In a system designed to maximize yeast activity, the substrate (sucrose or glucose) is utilized at a rate of 0.77–3.0 g of sugar per hour per gram of yeast solids. In a 3-h fermentation and 55-min proof, with compressed yeast (29 % solids) added at 2 % flour weight, that calculates to be 1.75–6.82 g of sugar per 100 g flour weight. Yeast utilizes sucrose following conversion to glucose and fructose by its efficient invertase enzyme system.

Carbon dioxide is retained in the bread dough in two phases: as a gas within the gas cells and dissolved in the aqueous phase. As carbon dioxide is produced it reacts to a small extent with water to produce carbonic acid and the pH decreases. Continued production of carbon dioxide soon leads to saturation of the aqueous phase. The apparent initial lag that is found in gas "production" curves for bread dough is because the aqueous phase of the dough must become saturated with carbon dioxide before its evolution or loss can be measured. Only after the aqueous phase has become saturated is the carbon dioxide available to leaven the system. Carbon dioxide solubility in water is inversely related to the temperature and affected by pH. At the pH of bread doughs, most of the carbon dioxide is present as CO_2 and only to a very small extent as H_2CO_3, HCO_3^-, or CO_3^{2-}. The carbon dioxide present in a fully proofed dough is only about 45 % of the total produced by fermentation. Part of it is lost during fermentation, punching, molding and proofing. The expansion of CO_2 in the

air cells and the CO_2 that comes out of the aqueous phase is insufficient to completely account for the increased volume of dough in the oven.

As fermentation proceeds, it is customary to punch or remix the dough, depending upon which baking system is used. The gas cells in the dough have become larger and larger as more gas is produced. Punching or remixing subdivides the gas cells to produce many smaller cells. During remixing, a large amount of CO_2 is lost to the atmosphere, but the important aspect of the process is the creation of the new gas cells. Another important benefit of punching or remixing is the mixing of the dough ingredients. Yeast cells are not mobile in dough. Therefore, they depend upon the diffusion of sugar to them. As fermentation proceeds, the diffusion distances become large, the concentration of this nutrient diminishes and along with it the rate of fermentation. Punching or remixing brings the yeast cells and fermentables together again. In zero- or short-time baking systems punching is not practiced, as the dough is not given sufficient time to expand. The net result is usually a coarser grain in the bread. A partial solution to this problem is to mix under partial vacuum. This increases the size of the bubbles and allows them to be subdivided into many small bubbles that contribute to a finer crumb texture.

In addition to producing gas, yeast also affects dough rheology. The effects of yeast on dough rheology can best be shown by a simple spread test [209]. Dough has both viscous-flow properties and elastic properties. Dough that has more viscous-flow properties has a large spread ratio (width of dough divided by height), whereas dough that is more elastic has a smaller one. A flour–water dough without yeast gives a larger spread ratio after 3 h than a yeast fermented flour–water dough (Fig. 5). This indicates that the viscous-flow properties are larger in flour–water dough. Thus, the addition of yeast to the formula causes a change in dough properties: the viscous-flow properties are reduced and the elastic properties are increased. It has been shown that the build-up of hydrogen peroxide produced by yeast during fermentation affects rheological dough properties [103].

Optimally fermented and oxidized dough has no viscous-flow properties under the force of gravity at the proof stage. Thus, the dough in the pan expands rather than flows to fill the pan. After fermentation, presumably because of the mechanical punching, the gluten fibrils appear to be aligned. The change in pH associated with fermentation time is also important to the dough's rheological properties. Dough just out of the mixer usually has a pH of about 6.0. During fermentation, the pH drops to 5.0. A rapid drop is caused at first by carbon dioxide dissolving in water to produce carbonic acid. A second factor is the slow production of organic acids by the bacteria in the dough. The flour itself and milk or soy proteins (if present in the formula) are good buffers and, therefore, help to control pH. A lower pH decreases the mixing time of dough. This is, at least in part, the reason for the shorter mixing time in a sponge-and-dough or preferment system than in a straight-dough system. However, the change in pH has little effect on the doughs spread ratio.

10.3. Gas Production by Chemical Leavening

Chemical leavening systems have been know since the first baking powder was formulated in 1838 in England and sodium bicarbonate is believed to have been used as a source of carbon dioxide since the 14th century. There are two basic types of chemical leavening: decomposition and chemical neutralization [210, 211]. Decom-

position, i.e. the breakdown of the leavening agent, takes place in the presence of moisture or heat. The most common example of decomposition is the use of ammonium bicarbonate that undergoes thermal decomposition at about 60 °C. When the product in the oven reaches this temperature, ammonium bicarbonate decomposes rapidly to ammonia, carbon dioxide, and water:

$$NH_4HCO_3 \rightarrow NH_3 + CO_2 + H_2O$$

Leavening by decomposition of ammonium bicarbonate can be used only in products that are thin and baked to low moisture levels (less than 5 %). If the product retains more than a few percent of water, it also retains the dissolved ammonia and even a small amount of ammonia in the product is associated with an off-flavor and makes the product inedible. Ammonium bicarbonate is used fairly widely in dry cookies and in some snack cracker type of products. It does have the advantage that it leaves no residual salt after decomposition. Residual salts can affect flavor, dough rheology or both.

Chemical neutralization is a process where a bicarbonate source is neutralized by an acid (HX) with release of carbon dioxide as leavening gas:

$$NaHCO_3 + HX \rightarrow NaX + H_2O + CO_2$$

Once the bicarbonate comes in contact with water in the dough or batter system, it quickly solubilizes and reacts with the acid under production of carbon dioxide. Since no ammonia is produced, this reaction is suited for leavening of high moisture baked goods. Carbon dioxide can exist as free CO_2, as HCO_3^- or CO_3^{2-}. The relative proportion of each is determined by the pH and temperature of the solution. The rate at which carbon dioxide is released from the bicarbonate depends on the rate at which the proton from the acid becomes available to react with the bicarbonate. No CO_2 is available if the pH stays above 8.0. Many soft wheat products end up with a pH near 7.0, where only a part of the carbon dioxide is in the gaseous state. To produce significant amounts of gas, the dough or batter must contain an acid. Many ingredients used in baking are sources of acid. Acidic fruits or buttermilk are obvious examples. If no acid is available natively, it is added to the formula. To determine the correct level of leavener and acid, the neutralizing value has been defined. It indicates the parts of weight of sodium bicarbonate that 100 parts by weight of leavening acid will neutralize. Thus, sufficient acidity to neutralize the bicarbonate and consequently, the release all of carbon dioxide is assured so that after baking there remains little, if any, unreacted bicarbonate or acid. Several acids are used in the baking industry. They all have distinct timing of release and reaction kinetics at various temperatures. Commonly used acids include cream of tartar (potassium hydrogen tartrate $KHC_4H_4O_6$), tartaric acid ($C_4H_6O_6$), δ-gluconolactone ($C_6O_6H_{10}$) and various sodium–aluminum–calcium phosphate compounds.

The most popular bicarbonate leavening agent is sodium bicarbonate (baking soda or soda). The popularity of sodium bicarbonate is due to its numerous advantages. It is relatively cheap, it is nontoxic, easy to handle, gives a relatively tasteless end product, and the commercially produced product is of high purity. Sodium bicarbonate decomposes when heated to about 90 °C in an aqueous system releasing half of the carbon dioxide released and the remainder becoming sodium carbonate.

Leavening systems used in industrial baking formulations are often tailor-made, comprising balanced blends of aerating chemicals to give a compound baking powder. These blends are adapted to the specific process requirements or constraints and to the desired organoleptic and technical product characteristics. They may combine various bicarbonates and acids and are either single- or double-acting. A double-acting baking powder is one that contains two acids, one that reacts (becomes soluble) at room temperature and another that reacts when the product is heated (heat-activated leavening agents). Encapsulated leavening agents perform by having the correct release and delivery kinetics. For example, encapsulated acids and encapsulated sodium bicarbonate are available as heat-activated leavening systems. Besides their leavening effect and, in some cases, their effect upon the product's taste by the salts produced during the leavening reaction, chemical leavening agents also can affect the rheology of the product. In general, di- or trivalent ions tend to increase the elasticity of the final product (especially cakes), and sulfate ions tend to decrease its elasticity. These ions presumably act by affecting ionic crosslinks with the proteins in the

batters. Dried starch is usually used as an inert diluent in baking powders. Its primary function is to physically separate the soda and acid particles and prevent their premature reaction.

10.4. Gas Retention

Bubble mechanics shows that the pressure P in a bubble is related to the radius of the bubble r and the interfacial tension γ by the following relationship:

$$P = \frac{2\gamma}{r}$$

Thus, in a system where the interfacial tension does not change, if r approaches zero, then the pressure required to start a new bubble is infinite. This implies that yeast can not create new bubbles in a dough system [212] and that air must be incorporated during mixing in the dough to provide preexisting bubbles (see Section 7.4).

In mixed bread dough, an insoluble but highly hydrated gluten protein system constitutes the continuous phase, with starch and air bubbles as the discontinuous phases. Also dispersed throughout the aqueous system are yeast cells, which ferment sugar and produce, among others, CO_2. The CO_2 is produced in the aqueous phase and saturates the water. Once the water is saturated, newly produced CO_2 must find a place to go. As discussed above, it cannot form new bubbles; thus, the CO_2 enters the preexisting air bubbles and increases the pressure. Dough has viscous flow properties and therefore, allows the bubble to expand to equalize the pressure. The CO_2 in the bubble cannot diffuse out because the aqueous phase surrounding the bubble is saturated with CO_2. Thus, the total volume of the dough mass is increased or, in other words, the dough is leavened. The use of ultrasound to investigate the cellular structure of bread and presumably dough has been described [213].

11. Molding and Proofing

After bulk fermentation, dough is divided into individual loaf-sized pieces, and is given a floor time. The purpose of this time is to allow the dough to relax. The dough is then ready for molding. The molding operation is essentially sheeting followed by curling, rolling, and application of pressure. As the dough is sheeted (passed between rolls to be flattened) during the various processes, it must be sheeted in different directions. Continued machining in one direction would align the protein fibrils and result in dough that is strong in one direction but weak in the direction at a 90° angle to the sheeting. After being molded, the loaf is panned. The dough is then ready for proofing. This is usually accomplished at 30–35 °C and at 85 % relative humidity. Because the dough now has only limited viscous-flow properties, it fills the pan by expansion. Proofing usually takes about 55–65 min; the dough increases greatly in volume. After proofing, the dough is ready for baking.

12. Baking

It is easy to tell the difference between dough and bread. The simple experiment of attempting to blow through dough shows that in dough gluten is continuous and the gas is discontinuous (in gas cells). Dough can be used to blow a bubble (e.g., in the alveograph). On the other hand, a slice of bread offers no resistance to the passage of air. Bread is not only gluten-continuous but also gas-continuous and is no longer capable of retaining gas [214].

However, the transformation of dough into bread, the conversion of the foam structure of the dough into the open sponge structure of the bread is a complex process involving irreversible changes (Fig. 6) [7, 133, 215 – 217]. Baking times and temperatures as well as baking temperature profiles vary widely, depending on the type of bread. Heat is transferred to the loaf mostly through the pan or baking hearth. In the crust and crumb, starch gelatinization, protein polymerization, and Maillard reactions (i.e., color and flavor generation) take place. Reactions inside the loaf (crumb) and at the surface (crust) are different because of the differences in moisture content and temperature.

12.1. Transformation of Dough into Bread

During the first few minutes in the oven, the dough expands rapidly in size (oven-spring or

Figure 6. Changes during the transformation of dough into bread.

oven-rise). Several factors are responsible for the oven-spring. As temperature increases gases increase in volume; carbon dioxide becomes less soluble; yeast becomes quite active in the initial phase of baking producing more CO_2 and ethanol; evaporation of CO_2 and the water–ethanol mixture during heating in the oven contributes greatly to the overall expansion of the dough. Generally the oven-spring stage lasts less than 8 min; the remaining baking time is to ensure that the center of the loaf approaches 100 °C.

If pan bread is produced, most of the heat that is absorbed by the dough comes through the baking pan. Therefore, the rate at which the dough temperature increases depends on the heat transfer from the air and the baking surface to the baking pan. Dough does not conduct heat as well as the metal pan; therefore, a well-defined temperature gradient forms from the outside to the center of the loaf during baking. The internal structure of dough that has been in the oven for various periods of time shows a sharp demarcation between dough and bread regions of each loaf (Fig. 7). This line of demarcation is consistent with the temperature gradient known to develop during baking.

When bread dough is baked in an electrical resistance oven the temperature gradients are, essentially, removed and the dough heats uniformly. When dough is baked by this method and, at the same time, carbon dioxide loss from the loaf is measured along with the dough temperature, the temperature at which the dough starts to lose carbon dioxide can be determined (Fig. 8). The question then arises as to how flour protein content and quality affect loaf volume. The wheat flour dough retains gas as the gas can only diffuse slowly through the complex gluten network. At higher protein content there is more gluten to cover the surface of the starch and air cells, thus, the gluten phase between the air cells is thicker than with low protein doughs. As the loaf expands in the oven the gluten is thinned to up the point where it is no longer extensible (strain hardened, [218]). In practice dough retains most of the carbon dioxide until the temperature reaches about 72 °C. Only at that temperature large amounts of carbon dioxide are released from the wheat dough/bread. This indicates that the temperature induces the loss of dough's ability to retain carbon dioxide. The stability of gas cell walls during baking is related to strain hardening [219].

The protein content of the flour controls the degree of expansion of the loaf. A higher flour protein content and/or a better flour protein quality allow the production of more expanded and high volume baked goods. Therefore, the baking performance of flours can be improved by incorporating additional vital wheat gluten into the formula. Doughs from nonwheat flours that do not form a continuous viscoelastic gluten ma-

Dotted line represents temperature increase.

trix are unable to retain carbon dioxide during heating (Fig. 8) and are therefore not suitable for bread making. However, good quality bread can be made from rye flour if an appropriate acidification is used (see Section 9.5). For wheat flour, the relationship between protein content and loaf volume is linear over the range of 8–18 % protein [220]. This effect of flour protein content on loaf volume is almost universally accepted. The proof height (volume) of dough containing different levels of protein is similar but the difference in height (volume) becomes much greater during the early stages of baking [221]. Thus, during the early stages of baking dough containing more protein expands at a much faster rate than dough with less protein. The protein

Figure 9. Scanning electron micrographs of the cross sections of dough (28 °C) and bread baked to 70 °C, 88 °C, and 95 °C.

content of the dough does not affect the loss of carbon dioxide during baking if the flour protein content is less than about 8.5 %.

By placing a thermocouple in dough as it baked in the electrical resistance oven it can be seen that the visual transformation from dough to bread occurs at 65 °C. However, the physical properties of dough continue to change it is heated to higher temperatures. Specifically the bread becomes stronger and more elastic. At 95 °C the bread has gone from a liquid to a solid state. The pressure becomes large enough to rupture the gas cell walls and produces the gas continuous sponge structure of baked bread. Scanning electron micrographs of dough/bread heated to below 70 °C show no tears in the gas cell walls while dough/bread heated to above 88 °C shows such tears (Fig. 9). The increase in strength of the bread structure, by itself, is not enough to keep the bread from collapsing or keyholing when it is removed from the oven. The pressure differential developed when the gas cools would cause the loaf to collapse. However, because the bread is gas continuous the pressure differential cannot develop and the bread does not collapse.

Occasionally, reference is found to changing the rate of baking. This is extremely difficult to do. The rate of baking is actually determined by the rate of heat penetration into the dough, and this cannot be changed. Increasing the oven temperature provides a larger gradient of temperature (ΔT) but that only speeds the rate slightly. The higher oven temperature results in larger

temperature and moisture gradients in the loaf but will not greatly change the time required to raise the center of the loaf to the desired temperature. Primarily the so-called Watt principle conveys heat to the interior of the loaf. The Watt principle states that moisture vapor will move to a cool surface where it condenses. In condensing, it gives up its latent heat and warms the cool surface. In a loaf of bread the moisture just under the crust is vaporized and moves toward the interior of the loaf (the cool surface) and condenses. The process is repeated until the center of the loaf reaches the desired temperature (near 100 °C). As a result of this process, immediately after coming from the oven, the center of the baked loaf will contain more moisture than what was present in the original dough. Of course, moisture is also lost from the dough surface during baking. The result is a large gradient of moisture content as the loaf comes from the oven. This gradient slowly disappears with time.

12.2. Crumb Grain Formation

The grain of a loaf of bread is not a random collection of cells but instead an organized system. In an aqueous environment with no added stress, gas cells are always spherical. They then have a minimum free energy and a minimum surface area. Spherical gas cells are clearly seen in cakes or in bread made with the continuous bread-making systems; therefore, there is no external force on the cells in those systems. In conventionally made bread, many of the cells are elongated, indicating that considerable force was put on the cells. The degree of elongation is a measure of the strength of the dough and a direct measure of the chewiness of the bread. With increasing flour strength, a trend toward increased loaf volume, more uniform crumb grain and stronger crumb was found [222].

During molding, the dough is sheeted and then rolled into a cylindrical form that causes elongation of the gas cells. If the dough is strong, the elongation persists through the proof stage. During baking, the crust on the exposed surface of the dough breaks at one or both sides where the crust meets the pan. As the break occurs, the loaf expands in that direction, giving a break and shred (i.e., an area where new dough is exposed to oven temperature as the loaf expands) on the exterior of the loaf and a nice slip plane (i.e., an area where the cells slide past each other as the dough expands) of elongated cells in the interior. If the loaf breaks on the other side, the grain is much less organized and more difficult, if not impossible, to judge. A fully oxidized and developed (matured) loaf has a large number of elongated cells, with a distinct slip plane. If the dough is underoxidized (termed green), many small round cells are evident and the slip plane is not distinct. Overoxidized dough gives loaves with larger round cells with thick cell walls and a very prominent slip plane, often containing large open cells. Thus, the grain of the loaf gives a reading on the oxidation requirement of the flour. In general, a larger volume and a more uniform crumb structure contribute to a softer baked product and improve the crumb softness during storage.

12.3. Crust Formation

When dough is placed in an oven, the surface that is exposed to the oven atmosphere skinsover and forms a crust almost immediately, since skin or crust formation is a result of surface drying. The expansion of the dough during baking is inhibited by the formation of the crust. Then, the moisture on the surface of the dough vaporizes rapidly, as it is in contact with dry, high-temperature air in the oven. The surface of the dough cools as the water vaporizes. If a thicker, heavier crust is desired, steam is generally added to the oven. The steam in the oven slows the rate of water vaporization, and the surface cooks to a greater extent, producing a thicker crust. The formation of a crust or skin has nothing to do with retention of gas, which is controlled by the properties of the interior of the dough and not by the surface.

Bread is a moist product; thus, although the baking temperatures exceed 200 °C, the temperature cannot exceed 100 °C unless pressure builds up in the product or the product becomes dry. The only part of the loaf that becomes dry is the crust, and this occurs late in the baking cycle. This is when browning takes place since the Maillard type browning reactions occur much faster in low moisture systems. Maillard reactions require the simultaneous presence of protein and reducing sugars. Sucrose is a nonre-

ducing sugar, but as stated above, yeast contains invertase, which rapidly produces glucose and fructose, both of which are reducing and brown quite readily. Other reactions in the crust might involve the thermal decomposition of biopolymers (starch, proteins).

12.4. Changes of Flour Constituents

Among the changes that are caused by heating a dough system are starch gelatinization and heat-setting of gluten polypeptides. In a bread dough, the starch starts to gelatinizes at about 65 °C. Gelatinization then proceeds over a wider temperature range dependent on water level/availability, formula ingredients, and baking temperature and time. Small amounts of amylose and degraded amylopectin are leached out of the starch granules and are released into the intergranular phase. Because of the limited amount of water in bread dough, essentially none of the starch is in solution [223]. Amylose can also form inclusion helices with polar lipids such as free fatty acids and monoacyl glycerols. Amylose in form of a single helix–lipid complex can not participate in double helix formation and thus, does not contribute to crumb firmness. This explains, in part, the softening effect of emulsifiers in bread production. Moreover, emulsifiers appear to retard crumb firming via reducing the swelling of starch. In addition, when efficient xylanases are used in the bread making recipe, significant levels of water-unextractable arabinoxylan are solubilized. During baking, the heat also induces the formation of disulfide crosslinks, thereby setting the gluten matrix. This process of gluten protein heat-setting contributes to the formation of the final bread structure and texture [80].

13. Flavor of Baked Products

The flavor of baked products is, together with texture and taste, the key sensory attribute responsible for the attractiveness of baked goods. Baked product flavor is generated from rather flavorless raw materials by two main processing steps, dough fermentation and the baking process. An important color and flavor generating reaction mechanism is the nonenzymatic Maillard reaction involving the reaction of reducing sugars with amino groups during baking [224]. Besides the processing conditions such as fermentation time or the type of microorganisms present in the dough, the recipe (type of flour, flour treatment, added fat, etc.) and storage conditions affect the overall aroma of the final product [225]. Volatile chemical compounds referred to as odorants elicit the overall bread aroma such as roasty–cracker-like, malty, caramel-like, sour, sweet, yeasty, or cake-like. Studies on volatiles that evoke the odor notes of bread in particular have shown that only a small number of volatiles are of significance in determining the flavor [226].

The overall odors of either wheat bread crust or crumb as well as those of rye bread crust or crumb are significantly different. The roasty smelling 2-acetyl-1-pyrroline (ACPY) is the key odorant evoking the pleasant note in the aroma profile of *wheat bread crust*. Ornithine, an amino acid occurring in baker's yeast was identified as the most effective flavor precursor of ACPY. In baguette production, the formation of the key odorants (ACPY and aldehydes) in the crust and thus the flavor profiles were shown to depend on the amount of yeast and the fermentation conditions [227].

In *wheat bread crumb*, three aldehydes and the two alcohols 3-methylbutanol (fermentation-like) and 2-phenylethanol (flowery) are the most potent odor-active compounds. The use of sour dough in wheat bread production leads to an increase in the concentration of these two alcohols and might contribute to the more intense flavor of sour dough- enriched wheat bread. The very low concentration of ACPY in wheat bread crumb might be explained by the nonavailability of the precursor ornithine. It is indeed possible that the high temperatures in the crust induce the disruption of yeast cells and consequently the release of ornithine, and that at lower temperatures in the crumb ornithin remains in the yeast cells.

ACPY disappears very rapidly after baking. This loss together with the formation of higher-stability odorants by lipid peroxidation, e.g., (*E*)-2-nonenal is involved in the formation of the stale off-flavor perceivable during storage of wheat bread.

In contrast to wheat bread crust, *rye bread crust* is very low in ACPY and much higher in

3-methylbutanal, methional, furanone and acetic acid. In *rye bread crumb*, phenylacetaldehyde, which is not present among the key odorants of wheat bread or rye bread crust, is an important odor active compound.

14. Glass Transition and its Role in Baking

The texture of baked products is strongly affected by their glass transition temperature (T_g). Regions in solid food products such as baked goods can exist in either a thermodynamically stable crystalline or in an amorphous, nonequilibrium state. In trying to understand the behavior of materials such as polymers (e.g., proteins, starch) and low molecular mass components such as sugar in their amorphous state, one of the most important properties to know is T_g [7, 228 – 238]. The T_g markedly determines many of the physical properties of a material. (For a definition of T_g, see → Plastics, General Survey, Section 6.2.5)

The overall concept of T_g and phase transitions can be summarized in the generalized 'state diagram' as shown in Figure 10. The state diagram defines the moisture content and temperature region at which a food domain shows glassy, rubbery or flow behavior. A food region composed of polymeric material has a higher T_g than a food region composed of lower molecular mass components. The level of plasticizer (e.g., water), along with the temperature, determines what state the region is in. The higher the concentration of plasticizer (water) in a food product, the lower is the glass transition temperature. Below the T_g curve, reactions occur very slowly because the food is in a glassy state and has a very high viscosity [239 – 241]. Molecular movement is decreased at this high viscosity except for small molecules such as oxygen or water vapor that can diffuse through larger pores. Above the T_g curve, viscosity decreases significantly. This allows increased movement of molecules, resulting in a soft/rubbery texture or, for example, in the rapid crystallization of sugar. From this plot it can be seen that if a product starts at point A in the glassy/crispy region and the temperature of the product is raised (Fig. 10 A → B), it will first become leathery, then rubbery, and eventually will flow. For example, for a bread with 37.4 % moisture a T_g of − 12 °C has been reported [242]. Softening starts at − 12 °C and then progresses continuously up to 100 °C. Likewise if the moisture content increases, the product can also go from glassy to leathery and rubbery (Fig. 10 A → C) even if the temperature remains constant.

Figure 10. Idealized state diagram of a cereal material as a function of temperature and moisture
A is the assumed starting point of a crispy baked product showing a glassy/crispy to rubbery/soggy phase transition as a result of a temperature (A → B) or moisture (A → C) increase

These alterations in moisture and temperature can have positive and negative effects on consumer acceptance of texture and there are many examples of glass transitions in baked products: crispy crust formation in bread due to dehydration during baking; toasting bread drives moisture out and restores the glassy state to the crust and, indeed, to the rest of the bread if sufficient moisture is removed; pizza crust becomes soggy in the presence of sauce; a baked cone filled with ice cream becomes less crisp over time; saltine crackers, that are crispy at low moisture contents, become rubbery and soggy when absorbing moisture from other adjacent food components such as cheese, jam, or a fruit paste of high moisture activity; cookies become rubbery when taking up moisture during storage or chocolate chip cookies change from a soft desired texture into a hard undesirable texture because of sugar crystallization over time; staling of bread is associated with the nonequilibrium phenomenon of starch recrystallization during storage (see Section 17.1).

15. Bread Varieties and Speciality Breads

Today, a great variety of speciality breads is available in the Western world. The great preponderance of the bread produced in the United States is white pan bread. However, in the 1990s, nonwhite or speciality bread has increased rapidly in popularity.

In the United States white breads that are not baked in a pan are also speciality breads. Included in this type are hearth breads of the French, Italian, and Vienna types and a number of hard rolls. Other than the obvious difference of being baked free-standing on a hearth rather than supported in a pan, the difference between pan bread and these loaves as made in the U.S. is not large. In general, steam is used in the baking oven to produce a thicker crust. In some shops, the formula is somewhat leaner (lower in fat, sugar, and milk) but not nearly as lean as the flour, water, salt, and yeast loaves of their European namesakes.

Wheat breads, breads made from 100 % whole wheats, as well as combinations of whole wheat and white flour are also types of breads that are rapidly growing in significance. To be labeled as a whole-wheat loaf in the United States or Germany, the bread must be made from whole-wheat flour of specified granulation derived from the whole wheat kernel. Loaves of this type are smaller and more compact, with a high density and lower volume. Most wheat bread produced in North America contains partly whole-wheat meal and partly strong white flour. This results in a much better loaf volume and a lighter-tasting product. Many bakers also add vital wheat gluten to such formulas to aid in improving the volume. The formula, other than the type of flour, does not vary greatly from that used for white pan bread.

In Europe, bread production techniques and specialties are very diverse [243]. The selection of bread available is mainly based on the use of wheat and rye flours. At the same time, barley and oats have always had a considerable role in the production of baked goods, originally due to the scarcity of wheat and rye, nowadays to provide more variety in breads. The cultivation of rye plays an essential role in European bread making and has contributed significantly to the development of various types of bread. In the North America bread made from 100 % rye flour is rarely seen. Most rye bread sold in the USA is made with white wheat flour with enough added rye flour to attain a desired flavor and appearance.

Every country has its own food specialties and in the following, France, Germany and the United Kingdom are briefly presented as examples of the European bread culture [244, 245].

France. In France, about 80 % of the bread is still produced in small bakeries. The most common traditionally eaten bread is the baguette. It represents more than 50 % of the French bread production. The baguette is a white wheat bread characterized by a long, thin, crusty loaf. It should be fresh and crunchy and the shelf life varies between 4 and 6 h. The proportion of the crust comprises 40–50 % of the total bread and crumb has an open grain and excellent flavor. Baguette is produced with four basic materials: flour, water, salt and yeast. Bread improvers might be added to correct possible flour deficiencies: lipoxygenase-active bean flour to improve whiteness, ascorbic acid to strengthen the dough, malt to provide α-amylase activity, and lecithin to improve gas retention. Other French speciality breads include the fine wheat bread (pain de gruau), the Viennese bread, and biscottes.

Germany. Baked products are divided into two types: the production of bread allows a maximum of 10 parts sugar and/or fat to 90 parts of flour; products with more than 10 parts sugar and/or fat to 90 parts of flour are called fine bakery wares (Feine Backwaren) [243, 244]. Bread is divided into five main groups: wheat breads (at least 90 % wheat), mixed wheat–rye breads (min. 50 % wheat), mixed rye–wheat breads (min. 50 % rye), rye breads (at least 90 % rye), and bread specialties. Each of the first four groups was established based on the proportion of wheat and rye in the formula. These groups are further classified into subgroups according to the type of milled raw materials used: low extraction flour bread, meal bread, and wholemeal bread. Speciality breads can be prepared, for example, by adding nonbread grains (e.g., oat, barley, rice, maize), raw materials of plant origin (e.g., oilseeds, germs, raisins), materials of animal origin (e.g., milk, butter, yogurt, whey) or by using special baking techniques (e.g., wood-heated

oven, steam oven, stone oven, crisp bread). From the total bread consumption, about 15 % is eaten as small rolls and its consumption is further increasing. The so-called nonbread grain breads have become very popular. Also the production of dark breads such as wholemeal flour breads is on the rise.

United Kingdom. The typical UK sandwich-bread has a high volume, soft texture, very fine porous crumb structure and is also characterized by long shelf live properties. Most of the bread in the UK is produced with the Chorleywood bread process that includes a high-speed mixing of the dough in the presence of an oxidizing agent. Speciality breads comprises germ breads with the addition of 10–25 % wheat germs, high protein bread with wheat gluten, milk, or sometimes soy protein. Malt bread produced in the United Kingdom is a sticky, sweet, dark loaf that might also contain dried fruit pieces. UK rye bread is usually made from a mixture (50 : 50) of white wheat flour and rye flour.

Sour dough breads, both rye and wheat, are popular in Europe and certain areas of the United States. The U.S. San Francisco sour dough bread is made from white wheat flour using sour dough as leavening agent. Typical sour dough breads such as rye bread or mixed rye–wheat bread are often produced as round loaves and baked in ovens with steam to give a heavy crust. The sour dough technology is also applied to typical Italian baked products such as Panettone, Pandoro, Veneziana cakes, Pugliese bread, and brioches as well as to certain gingerbread cookies and crackers. Depending on the level of sour dough used, baked products made with sour dough are characterized by a sour-aromatic taste and better shelf life properties.

Flat Breads. Another major use of wheat flour is in the production of flat breads [246 – 248]. In Central America, North Africa, the Middle East, the Southern States of the former Soviet Union, India, and in Scandinavia these breads represent a major source of calories and protein. Flat breads are prepared from one flour or a flour mixture made from wheat, corn, rye, barley, sorghum, millet, or rice grain. Based on the cross-section of these products, they can be divided into two groups, single-layered and double-layered. Single layered flat breads include tortillas, chapati, foccacia, naan, pizza crust, and Scandinavian crisp bread. Wheat tortillas have exhibited increased consumption and market growth in the United States and large-scale commercial production has become common in Mexico and parts of the United States [249, 250]. Typical examples of double-layered flat breads are Arabic (pita) and baladi bread.

Steamed Bread. In some parts of Asia, especially in northern China, steamed bread is a staple item in the diet [251]. A large part of the country's domestic and imported wheat is used to produce steamed bread. Steamed bread is prepared by cooking or steaming a fermented dough. Therefore, steamed bread does not have, in contrast to Western-style breads, a crust but rather a soft, smooth, thin skin. The color of the external skin and internal crumb should be very white. Steamed bread has a symmetrical, well-rounded shape and a moist, elastic, springy crumb texture and is eaten as plain bread or filled with meat, vegetables, or sweet ingredients.

16. Soft Wheat Products

The diversity of products made from soft wheat flour (North American terminology) is amazing. Unlike hard wheat flour (same terminology), which is used for one major product, bread, and numerous minor ones, soft wheat has more than one major use. The baked products made from soft wheat flour can be grouped as follows, however, with a wide variation within each of these groups: (1) biscuits/cookies, crackers, and wafers, (2) cakes, (3) pastry products from pie crusts to puff pastries, and (4) waffles, pancakes, and donuts. According to this product variation, large differences exist in formulas (Table 1) and processing technologies. In the following, the discussion will concentrate on the biscuits/cookies, crackers, wafers, and pastry products to explain the technology and underlying principles of their production. Other nonbaked product applications for soft wheat flour include oriental noodles, thickeners for soups and soup mixes, manufacture of crumb for coating fish and meat products, and as the basis for

some breakfast cereals. All of the above products have better appearance and eating quality when made from soft rather than hard wheat flour. Soft wheat is used in these applications because (1) the stronger gluten and higher protein levels of hard wheat would reduce the quality of the above mentioned products, (2) soft wheat flours have lower levels of damaged starch and therefore lower water absorption and viscosity, and (3) soft wheat flours have a finer texture and smaller particle size distribution [10, 112, 252, 253].

Cookies/biscuits, crackers, and pastries contain generally high percentages of sugar and/or fat relative to flour and a relatively small percentage of water. This overall composition separates this group of baked products from breads, that contain relatively low levels of sugar and fat and intermediate levels of water, and from cake-type products that have high levels of fat and sugar, but also water. The low moisture content of cookies/biscuits and crackers confers a long shelf life to these products and also gives them a relatively high caloric density. Because of these properties, biscuits and crackers have a firm place in the diet of some parts of the world such as in South America. They are staple food and eaten often as bread replacer. Within the various types of cookies and crackers, large differences in composition can occur.

16.1. Technology of Cookie and Cracker Production [7, 254 – 258]

Ingredients for biscuit and cracker making include dry (e.g., wheat flour, sugar, starches), liquid (e.g., fats and oils, syrups) and minor ingredients (e.g., leavening agents, emulsifiers). Most large biscuit factories receive and store their major ingredients in bulk, i.e., not packed but in containers of a given size. The ingredients are pre-processed (sieving, filtering, blending) and then metered automatically into the dough mixer.

The majority of dough mixers used for the preparation of cookie and cracker doughs fall into one of three categories; i.e., vertical spindle mixers, high-speed mixers (horizontal drum mixers) and continuous mixers. *Vertical spindle mixers* operate at slow speed and therefore have a gentle mixing action. This type of mixer is widely used in the USA for mixing cracker doughs. *High-speed mixers* are widely used in modern cookie bakeries and are particularly useful for mixing stiff, tight doughs that require considerable amounts of work input. *Continuous mixers* are mainly used in large, dedicated production lines. After mixing, doughs are left to relax or ferment from 30–45 min for cookie doughs, to 2–3 h for chemically leavened crackers doughs and up to 24 h for yeast fermented cracker doughs. The dough then goes to a forming stage prior to baking.

Large scale biscuit and cracker baking is carried out in band ovens (traveling oven) varying in length from about 30 to about 150 m. The products travel through an oven tunnel on a continuous band of solid steel or a woven wire mesh which may be up to 1.2 m wide. The tunnel is heated internally either directly (e.g., by gas or electric heaters within the baking chamber–direct gas fire) or indirectly by hot air circulated through the oven from an external source (convection–indirect ovens) or by a combination of the two systems. Baking times vary from about 1 min to about 15 min and baking temperatures from about 200 °C to 240 °C according to the product. The completion of the baking process is generally judged by two product properties: its color and its moisture content. To better control process conditions and final product properties of cookies and crackers, the baking process has been studied by mathematical modeling [259, 260]. This approach takes into account parameters such as oven and cookie temperature, baking time, throughput, turbulence, humidity of the oven atmosphere, properties of dough pieces and cookies (e.g., cookie dimensional data, moisture, color) to build models for oven design and optimized and standardized finished product quality.

After baking, cookies/biscuits and crackers are transferred to a cooling band prior to being packed. In some cases, cookies/biscuits are subjected to further secondary processes after cooling such as coating or sandwiching (e.g., with chocolate, fat-based creams, jam, jelly) to achieve a greater variety of flavors, textures, and appearance.

Table 1. Average dough recipes of soft wheat products: parts of ingredient based on 100 parts of flour (by weight)

	Cookie	Cake	Pound cake	Short pasty	Puff pasty	Croissants
Flour	100	100	100	100	100	100
Dough fat	30	50	100	45	20	15
Lamininating fat	–	–	–	–	80	45
Water	25	140	–	23	52	58
Sugar	50	11	100	< 70	–	3
Others (e.g., egg, milk)	100	17	100	–	–	10

16.2. Cookies

In general, cookies are characterized, by a formula high in sugar and fat/shortening and relatively low in water. The products called "cookies" in the United States correspond to similar products called "biscuits" in Europe and the United Kingdom. The biscuits made in the United States are more accurately defined as chemically leavened bread. The diversity of cookie products is quite wide; cookies as well as crackers not only vary in formula but also in type of manufacture (Fig. 11) [258].

Figure 11. Composition of various types of cookies/biscuits and crackers
Proportions of flour solids, fat, and total dry sugars are expressed as percentages of the dry product. Hard doughs: •; short doughs, sheeted and cut: O; rotary molded: □; soft doughs, wire-cut: x [258]

In *soft cookie* doughs, in general, gluten should not be developed during mixing. Development of the gluten leads to tougher products and generally to cookies that will not spread. The retarding of gluten development is not much of a problem. The low water content (about 10–20 %), the high sugar and high fat content in most cookie formulas result in a dough in which the gluten is not developed since the hydration of protein is insufficient to allow gluten network formation. Therefore, the dough is of soft consistency and has little or no cohesive properties. In the United Kingdom, such dough is termed a *short dough* and or *short sweet dough* and is related to cake formulations except that it contains much less water. The majority of these short doughs are processed into the desired shapes by compression into dies engraved on a designed roller (rotary-mold cookies) or by extrusion and subsequent cutting to the required size by an oscillating wire (wire-cut cookies) or by a guillotine (bar-press cookies) (see Section 16.2.1).

The other basic type of cookie dough is referred to as *hard dough*. The hard doughs are related to bread doughs but are of much stiffer consistency and give products that are somewhat tougher with a firmer bite than soft dough products. Hard doughs contain more water (about 20–30 %) and less sugar than soft doughs, thereby allowing gluten development during mixing and subsequent processing. Therefore, these doughs exhibit, like bread doughs, viscoelastic properties and require rolling with heavy steel rolls to form dough sheets of the required thickness before the dough is cut out from it (cutting machine cookies: e.g., rotary-cut cookies). The gluten development stops spreading during baking of this type of cookie.

16.2.1. Cookie Types

Rotary-Mold Cookies. For this type of cookie, the dough is forced into molds on a rotating roll. As the roll completes a half turn, the dough is extracted from the cavity and placed on the band for baking. The consistency of the dough must be such that it will feed into the cavity with no voids but still be extracted from the cavity without being distorted. Formulations for rotary-mold cookies are characterized by fairly

high sugar and shortening levels and very low levels of water (< 20 % based on the flour and including the moisture in the flour). The typical dough is crumbly, lumpy, and stiff, with virtually no elasticity as the gluten in the dough does not develop during mixing. Therefore, the cookie does not rise during baking and the design embossed on the cookie will not be distorted. Much of the cohesiveness of this type of dough comes from the plastic shortening used. Rotary-mold cookies are economical to produce. A small amount of water is added to the dough and, therefore, less energy is required to remove it during baking.

Wire-Cut Cookies. A relatively soft dough is extruded through an orifice and cut to size, usually by a reciprocating wire. The dough must be cohesive enough to hold together, yet short enough to separate cleanly when cut by the wire. A typical formulation, based on flour weight, may contain 50–75 % sugar, 50–60 % shortening, and up to 15 % eggs. Wire-cut machines can handle a range of cookie doughs, and a wide variety of products can be made. Wire-cut cookies rise and spread or flow during the baking process and they are of much softer consistency than rotary mold cookies. The final size of the cookie is determined by the formula and the flour used. In addition to such common examples of this cookie type like sugar-snap, chocolate-chip, or oatmeal cookies, also fig or date bars can be coextruded and subsequently wire-cut.

Cutting-Machine Cookies. The process for this type of cookie includes both rotary-cut and stamped doughs. The dough is made into a continuous sheet and the product cut out from it. Typical examples are animal shaped cookies, gingerbread men, etc. The formula contains much more water than do formulas used with a rotary mold. The sugar content is relatively low compared to most other types of cookies. Because a sheet of dough is made, the gluten is developed in this system. The gluten development stops spread during baking of this type of cookie.

16.2.2. Underlying Mechanisms of Cookie Baking

In general, cookie quality includes (1) the size of the cookie, both the width and the height, (2) the eating quality and mouthfeel (i.e., cookie bite, good quality cookies must have a tender bite), and (3) the appearance including color and surface cracking (top grain).

To evaluate the effects of flour properties, formula ingredients and process parameters on cookie quality a cookie must be baked. Two American Association of Cereal Chemists (AACC) cookie formulations — the wire-cut formula and the sugar-snap formula — were developed to study the effects of flour quality (e.g., wheat cultivar differences) on cookie properties [261]. The most widely used baking procedure to evaluate soft wheat flours is the AACC sugar-snap cookie baking test. It is reproducible and very sensitive to changes in both flours and formulations. A prediction equation for sugar-snap cookie diameter that uses sucrose solvent retention capacity, wheat milling softness and flour protein content has been reported to be useful [262].

When a cookie dough is heated in an oven, a number of events occur that are related to structural and dimensional changes, loss of moisture, and the development of color and flavor [7, 224, 258]. These changes occur in three successive, albeit overlapping stages. In the first stage the dough piece increases in thickness due to aeration and moisture loss commences. In the second stage the product "sets", i.e., cookie spread stops and moisture loss reaches its maximum. In the third stage, coloring of the cookies occurs. Thermal events that occur during heating sugar-snap cookie dough have been attributed to the melting of fat, and the dissolution of sugar [7]. First, the fat (shortening) in the dough melts. Thus, the dough containing melted shortening is more free to flow under the force of gravity. The second thermal event is dissolution of the sugar. The formula for the simple sugar snap cookie is high in both sugar (60 % of flour weight) and shortening and relatively low in water (about 24 % of flour weight). As a result of those ratios and the creaming step (mixing the sugar and shortening) only about half the sugar is dissolved during mixing; the remainder stays in a crystalline form until the dough is heated. Then that sugar

dissolves. When sugar dissolves, it increases the volume of solution in the system. Each gram of sugar, when dissolved in 1.0 g of water, produces about 1.6 cm^3 of solution. The increase in total solution also has a pronounced effect on the cookie dough. The increased solvent content makes it sticky. Likewise, cookie dough prepared with sugar syrup rather than crystalline sucrose is sticky and does not machine well.

Figure 12. Time-lapse photographs of cookies made from excellent and poor-quality cookie flour (reprinted from [265]).

Time-lapse photography has been used to monitor the kinetics of changes in visual appearance (e.g., surface cracking) and geometry such as the development of cookie spread during the cookie baking process [263 – 265]. As demonstrated in Figure 12, the lateral and vertical dimensional changes of sugar-snap cookies during baking are markedly affected by the flour quality. A poor cookie flour (i.e., hard wheat flour with high protein content $> 10\,\%$) and an excellent cookie flour (i.e., soft wheat flour with low protein content, ca: 8–9 %) was used for cookie dough preparation. Early baking behavior (1–2 min) is similar for both poor- and excellent cookie flour doughs. Both types of cookies expand in width and height due to the production of leavening gases from the sodium–ammonium bicarbonate leavening system. By the third minute of the baking cycle, the cookie baked from excellent cookie flour spreads more rapidly and continues to spread for a longer period during baking than the cookie from the poor cookie flour. The cookie made from poor cookie flour is capable of withstanding collapse during baking [264]. In contrast, cookies made from excellent cookie flours cannot support their own weight against uncontrolled, structural collapse under gravitational force. The expansion (increased cookie diameter) and decreased cookie height are accompanied by progressive structural collapse throughout the baking cycle with the most dramatic phase of collapse occurring in the last minute of the 10 min baking cycle.

Cookie expansion and lateral flow have been related to the viscosity of the system. At baking temperatures the cookie dough made from excellent cookie flour has a lower viscosity than the cookie dough made from poor cookie flour and thus shows more expansion due to of leavening and faster flow under gravity. Since both, gravity and the amount of leavening agents are constant, the question arises of what are the underlying mechanisms of the viscosity of cookie doughs are. While starch and soluble starch in the wheat flour may affect cookie spread [263, 266], starch gelatinization can be ruled out as contribution to the different viscosities of the two cookie systems. Due to the low water and high sugar content of the cookie starch does not gelatinize or only to a limited extent. It appears that the viscosity changes during baking are related to the wheat proteins. The wheat proteins in a sugar-snap cookie formula are not developed into a continuous gluten network during mixing. When the dough is heated during baking, the wheat gluten proteins go through their glass transition (see Chap. 14), thereby gaining mobility that allows them to interact and to form a continuous gluten phase. The viscosity of this continuous gluten phase is sufficient to stop the flow of the cookie dough [267]. In cookie doughs from poor, i.e., hard wheat flours, this gluten network appears to be sufficiently strong to account for the resistance to expansion and flow (i.e., spread) during baking and the prevention of structural collapse [145, 147].

The overall importance of bread has favored the breeding and growing of harder wheat flours with higher protein contents. The proteins of

these hard wheat flours, specifically the high molecular mass glutenins, that form a strong gluten network are detrimental to the baking of cookies and crackers. Consequently, sulfite compounds (e.g., sodium metabisulfite $Na_2S_2O_5$) have become widespread in the cookie manufacture to rapidly break down wheat proteins by rupture of disulfide bonds. From the sulfite compounds added, traces may remain in the final product. This has led to a ban of these chemicals in most countries and to investigations into alternative ways of controlling dough rheology such as the use of proteolytic enzymes.

Apart from gluten structural effects on viscosity, sucrose as a major ingredient in the cookie system is likely to play a role in the differences of cookie diameter when hard and soft flours are used for cookie baking [238, 263, 264]. Sucrose can act as plasticizer but it is much less effective than water due to its larger molecular mass. Antiplasticizing agents increase the glass transition temperature (see Chap. 14). Therefore, in comparison to water, sucrose may have an effect by acting as an antiplasticizer. The T_g of a cookie dough made from excellent (soft, low protein) flour is raised to higher temperatures than the T_g of a cookie dough made from poor (hard, high protein) flour. Since setting, i.e., stop of cookie spread, is possible when the cookie system goes through T_g and thus into the flexible/rubbery region (where gluten proteins can form a network that increases the viscosity to a degree sufficient to stop flow of the dough), doughs from excellent wheats would have more time to spread, resulting in a larger cookie diameter [267].

16.2.2.1. Texture Development of Cookies

A cookie can be described as a brittle matrix in which gas bubbles of various size and shape are embedded. The mechanical properties and fracture behaviors of a cookie are affected by the volume fraction and distribution of each phase and by interactions between the various phases [268 – 270]. Recipe (Fig. 11) and process conditions strongly affect the textural properties of the final cookie product.

The nice tender bite that is associated with good quality cookies appears to be related to several factors:

1) The air volume fraction and the degree of inhomogeneities of the cookie (e.g., size and shape of gas cells, material thickness between gas cells) determine its textural properties. Fracture starts from large size defects (i.e., gas cells) [268]. This crack initiation is then followed by crack propagation.
2) The use of fat or shortening produces a short product (see Section 16.7.1, the word "shortening" came from this usage). Reduction of the fat content is generally accompanied by an increase in modulus of elasticity and fracture stress. In the brittle cookie matrix, fat acts as a filler at low concentrations (about 16 wt % fat) (fat dispersed system) or forms a partly continuous phase at high concentrations (about 28 wt %) (fat continuous system) [269]. Fat also affects the flavor release and delivery of a cookie.
3) The flour strongly impacts the textural properties of a cookie. Generally, a soft wheat flour gives products with a tender bite.
4) Type and physical state (glassy/crystalline) of sucrose: Essentially all cookies, except those that are dried to a very low moisture content, are soft and quite flexible when they come out of the oven. With time, they become firm and often brittle. This appears to be related to the crystallization of sucrose. When the sugar dissolves, the syrup gives the cookie flexibility. In order to maintain a soft cookie, only a sugar or other substance needs to be added that interferes with sucrose recrystallization.
5) The moisture content markedly affects cookie texture. The final moisture content of a freshly baked cookie is usually within the range of 1–5 % that is associated with a water activity (α_w) of about 0.1. This residual moisture however, is not uniformly distributed throughout the product. A moisture gradient exists with the highest moisture content occurring in a thin lamella near the product center and the lowest moisture content occurs at the periphery and product surface. This moisture gradient disappears by migration and redistribution of moisture from the center to the surface of the product during cooling and storage. Firm cookies, i.e., snap-cookies such as sugar- and ginger-snaps, are baked to lower moisture content than are soft cookies. For a cookie to remain soft it must have a relatively high moisture content after baking.

Using two doughs that are kept separate can make a dual-texture cookie. One contains sucrose and the other a crystallization inhibitor (corn syrup). To maintain softness, hygroscopic sugars such as glucose and fructose are very effective. To maintain the crisp or soft texture, cookies must be stored under low or high relative humidity, respectively, which requires appropriate packaging material.

16.2.2.2. Development of the Cookie Surface Pattern

For certain cookies such as sugar-snap cookies and gingersnaps, the development of a cracking pattern on the surface called 'top grain' is desired. This cracking pattern develops during baking and the phenomenon has been explained as follows. Moisture is lost from the surface of the cookie at a rapid rate during baking. The hot air in the oven has the capacity to hold a large level of water. As the water from the surface is lost, it is replaced by water diffusing from the interior of the cookie, and the sugar, not being volatile, is concentrated. Then, sugar will crystallize at the surface of the cookie and will no longer hold the water that gives a moist and moldable surface. Thus, the surface dries and as the leavening system expands the cookie the surface breaks to form the typical cracked pattern. Small levels of high-fructose corn syrup or certain other sugars interfere with sucrose crystallizing and thus destroy the cracking ability. It has also been proposed that the cookie collapse mechanism is associated with the increase of surface cracking, and thus, the development of top grain [264].

16.3. Crackers

As with cookies, the definition of crackers is quite broad. In general, crackers contain little or no sugar but moderate to high (10–20 %) levels of fat, based on flour weight (Fig. 11). The doughs generally contain low levels of water (20–30 %). In the USA the term cracker is applied to products made from flour and fat with contents of sugar varying from zero to about 40 % (flour weight basis) and includes at one extreme saltines and, at the other, products such as honey Grahams. In the UK the term cracker is traditionally reserved for products made from flour and fat with little, if any, added sugar. These products include cream crackers (made from fermented dough) and water biscuits. Another group of products known as semisweet biscuits, contain about 20–30 % sugar on flour weight basis. Although the formula of these products in terms of flour, fat, and sugar is not dissimilar to that of Graham type crackers the appearance and eating qualities of these UK products — which include rich tea, morning coffee, thin arrowroot, etc., crackers — bear no resemblance to American crackers.

Crackers are often prepared from yeast-fermented doughs. The best-known crackers made from fermented doughs in the USA are soda crackers, or saltines. The corresponding product in the UK is the cream cracker. Compared to cream crackers, soda crackers contain less fat and are slightly alkaline (pH > 7.0) due to the higher amount of sodium bicarbonate in the soda cracker formulation. Although very different in appearance and eating quality both products are usually made by a sponge and dough process with long fermentation times (up to 24 h total). These long fermentation times are associated with the specific texture and flavor development of these products. Usually, the 'sponge' made from flour, yeast and water is fermented for about 18 h. This fermentation step involves the growth of yeast added in the formulation and several species of lactic acid bacteria. Thereby, acidity is formed and the pH drops from about 6 to 4. At pH 4, a proteolytic enzyme present in flour has its optimum and appears to modify dough proteins so as to become less elastic.

After its fermentation, the sponge is mixed with fat, salt, sodium bicarbonate and the rest of the flour to form a dough which is allowed to ferment for further 5 h. The level of sodium bicarbonate in soda crackers doughs is sufficient to bring the dough pH to above 7. After 24 h the dough is ready to be processed. There is a trend to shorten the fermentation time but keeping the quality advantages of the sponge dough procedure. The application of liquid fermentation (lactic acid bacteria, yeast culture, flour and/or flour fractions, and water) has allowed to shorten the fermentation time to < 4 h and to improve

process control, to reduce floor space and capital investment (see Section 9.3).

After laminating, layering and sheeting the cracker dough is cut and docked. The purpose of docking is to pin the dough together (attach the top and bottom surfaces together) so it will not separate into layers. After docking, the dough is salted and baked for about 2.5 min at 260 °C to a final moisture content of about 2 %. The rapid heating during baking is accompanied by a rapid increase in water vapor pressure that causes puffing and separation of the layers of the cracker between the points tied together by the docking holes. Special packaging is required to maintain the low moisture level of the product, as even small increases in moisture decrease the desirability of the cracker.

Other cracker types include snack crackers that vary much more widely in formula than do soda crackers. In general, snack crackers do not contain yeast and are chemically leavened. They contain more shortening and much higher levels of flavoring materials. Often, the texture of snack crackers is denser than that of soda crackers.

16.4. Wafers

Wafers and wafer products are generally regarded by the consumer as biscuits and biscuit companies frequently manufacture them. Wafer making, however, has little in common with cookie or cracker formulations and process technology. The principle ingredients in wafer-making are wheat flour and water. Minor ingredients comprise small amounts of oil and/or lecithin, salt, sugar and aerating agents (sodium/ ammonium bicarbonate for nonfermented batters or yeast for fermented batters) that affect texture, flavor and color of the final wafer. The major function of bicarbonate is to adjust the pH, not to act as a leavening agent. The ingredients are mixed under high-speed to a fluid, homogenous batter containing up to 65 % water. The batter is distributed to the wafer-baking plate via a depositor. If gluten aggregates, strands and lumps are formed during batter mixing and pumping, they may cause blockages in the pipework, metering pumps, and batter depositors. Gluten aggregation can be controlled by the selection of flour quality [271] and adjusting process conditions (batter temperature, mixing speed). Often, commercial enzymes comprising a mixture of protease and arabinoxylanases are used in wafer manufacture to control batter viscosity and to avoid gluten aggregation (see Section page 15).

After batter depositing, the wafer is baked between a pair of heated, engraved metal plates for 1.5 to 3 min at about 180–200 °C. During wafer baking starch completely gelatinizes in the high-moisture environment. The water in the batter evaporates from the closed-plate system as steam through vent channels making water vapor the main aerating agent. At the end of the baking process, a dried (1–3 % moisture), highly aerated starch gel is formed with wheat protein interspersed in the starch matrix.

After baking, a filling is placed between the various wafer sheets followed by cutting the layers into "books". The filling generally consists of fat, sugar, flavors, and ground scrap product (rework) originating from wafer cutting. Variations in moisture contents among the wafers result in moisture transfers and a concomitant contraction and expansion of the wafer. This change in geometry can weaken the adhesion between the wafer and the filling or lead to cracking of a chocolate coating. Therefore, wafers are conditioned or matured, i.e., equilibrated under controlled atmosphere to ensure equilibration of the moisture in the wafer sheets before further processing.

Sugar wafers are made from batters containing a high level of sucrose (up to 60 % on flour weight). Such products, while still hot from the baking process, are quite flexible and may be rolled round a mandrel to form ice cream cones or folded to form a decorative fan or other shaped product that become firm and very brittle upon cooling.

16.5. American Biscuits

The American biscuit, actually a chemically leavened bread or bun, is typical to the United States and has only recently been introduced into the European market. In the USA it has become quite popular, particularly in fast-food establishments. The use of chemical leavening gives dough that results in a rather thick cell wall and a coarse grain in the final product. The flavor is strongly influenced by the taste of the soda

and the leavening acid. The production process is quite simple: the dough is mixed, sheeted to a desired thickness, cut, and baked.

A variation of the chemically leavened biscuit is the type sold refrigerated and packed in cans. The cans are actually foil-lined cardboard containers. The dough is mixed, sheeted, cut to size, and placed in the can. The volume of dough added to the can is much less than the volume of the can. The ratio of the two volumes must be carefully controlled. After the cans are sealed, they are placed in a proof box at a temperature high enough to trigger the leavening system but low enough not to hurt the dough properties. The dough then "proofs" i.e., expands to fill and caulk the can. The excess air present in the can is expressed through the can, which is permeable to air but not to dough. The dough builds a pressure of about 100 kPa (15 psi) and in this condition is quite stable for reasonable periods of time (60–90 d). Because the dough is not sterile, organisms will eventually destroy the quality of the biscuit. The bacteria can cause the pH drop, the pressure in the can to increases to dangerous levels, and the dough to become very short. Those factors limit the shelf life of the product.

The leavening acid for refrigerated biscuits must meet strict requirements. It must not react during mixing or sheeting of the dough but must react in the proofroom. This requirement is met only by the slow acting sodium acid pyrophosphate (SAPP). A number of different SAPPs are on the market. They vary in their reaction rates, i.e., in their release of CO_2. SAPPs are used widely in canned biscuits and in cake doughnuts, both of which have unique leavening requirements that are handled only by SAPPs. The major problem with SAPPs is the "aftertaste" that they leave in the mouth and on the teeth. Their so-called "pyro" taste is quite noticeable in these products. It apparently comes from the exchange of calcium from the teeth for the sodium in the disodium phosphate that results from the leavening reaction and is the result of the enzyme action that splits the pyrophosphate. Attempts to limit the effect of the disodium phosphate by adding various forms of calcium to the formula have been only partially successful.

16.6. Cakes

Cakes include a wide range of products of various types and sizes such as sponges, high ratio cakes, heavily fruited cakes, from cup cakes to wedding cakes and prepared cake mixes. Cakes, like cookies, are characterized by a high level of sugar in the formula. The major difference between the two is that cakes also contain relatively high levels of water. Because of the higher water level, starch can gelatinize and the cake sets during baking to a light, tender product that is characterized by a multitude of evenly distributed minute cells without any large holes [7, 210, 272].

16.6.1. Cake Making and Underlying Mechanisms of Cake Baking

Cake making starts from mixing a batter that is different from a cookie, cracker, or bread dough. Most important for all cake-making methods is the incorporation of small air bubbles into the batter since they act as nuclei for the expansion of the cake. The cake-making methods can be divided into two basic types, depending upon how the air is incorporated into the batter: multistage mixing and single-stage mixing.

Multistage Mixing. This is the classic procedure of high quality cake making, say, Madeira cake. It starts with a creaming step. Whipping air into the fat in finely distributed bubbles makes a fat–sugar cream. The air bubbles are dispersed in the continuous oil phase and stabilized by small, relatively stable β' fat crystals (needles of about 1 µm length; the polymorphic forms of fat crystals are named α, β' and β in order of increasing stability) distributed around the bubbles. Creaming steps are also used for certain types of cookies. Creaming offers a number of advantages; for example, a large number of air cells can be formed, leading to a fine cake texture. Also, the batter is stable and can sit for extended periods of time because the air is incorporated into the fat phase, where it is immobile and stable. Two and even three subsequent mixing steps then incorporate the liquids (egg, milk) and flour to form the final batter. This procedure allows the fat/air particles to be very finely distributed throughout the batter. The finer the distribution of fat and air, the better are the final cake volume and

crumb structure and texture. During baking, fat melts and separates from the air bubbles. The air bubbles move into the aqueous phase to generate a foam that is stabilized by egg protein. As heating proceeds, the air bubbles act as nuclei into which the carbon dioxide and water vapor diffuse to increase the volume of the batter. Then starch gelatinizes in the high sugar system, egg proteins coagulate, and the structure becomes set at about 95 °C.

Single-Stage Mixing. This type of cake making is typically used for sponge cake production. The liquids (water/milk and eggs) are mixed with the flour and the air is then incorporated into the aqueous phase. This is normally accomplished by mechanical means, i.e., high-speed mixing. When the air is incorporated into the aqueous phase, the fat (shortening) crystals of the cake formulation become coated with an interfacial layer of absorbed protein in the aqueous batter phase and then absorb to the air–water interface [273]. This mechanism helps to stabilize the large number of small air bubbles, to reduce coalescence of bubbles and the formation of larger bubbles during heating. Variations in bubble size and the presence of large bubbles result in an unstable mix, producing cakes of coarse and uneven texture. Gas can diffuse in a batter: gas diffuses out of the small bubbles into the aqueous phase and then into the larger bubbles because the pressure in a small bubble is larger than the pressure in a large bubble. Thus, there is a tendency for the small bubbles to disappear and the large bubbles to become larger. Because of the greater buoyancy the larger bubbles will overcome the high viscosity in the batter, rise to the surface and be lost. Hence, cake batters prepared by direct incorporation of air into the aqueous phase are not very stable and should not be allowed to sit for long periods of time before being baked.

A cake batter made by single-stage mixing can be regarded as an emulsion of the air-in-water type with air bubbles entrapped into the aqueous phase. During baking, the fat crystals melt to cover the internal surface of the bubble thus permitting bubble expansion without rupture. The volume of a cake batter is increased by about 3.5 times during baking as a result of the expansion of gases (air and carbon dioxide if baking powder is used) together with the vapor pressure (conversion of water into steam) within the bubble. Starch gelatinization and coagulation of egg proteins finally stop the process of bubble expansion and coalescence. Starch gelatinization is responsible for the dramatic increase in batter viscosity and is the first step in cake setting, i.e., the transformation from a liquid/foam to a solid sponge system. Because the molar sugar concentration is much lower in a cake than in a cookie formula, the starch can gelatinize during cake baking and prevents structural collapse of the finished product. The structure, volume and appearance of sponge cake depend on the levels of baking powder and emulsifier (monoacyl glycerol) and specific batter gravities as well as on ingredient-process interactions [274].

Box Cakes. All dry ingredients are sold to the customer in a box. Generally, the homemaker adds water, eggs, and oil to the mix and the batter is produced. The surfactants in the mix lower the interfacial tension and allow the air to be incorporated directly. Propylene glycol monostearate (PGMS) is a common surfactant used for this purpose. This type of cake mix must be run through a cake finisher that is essentially a grinder. Apparently, the purpose of the finishing is to bind the fat to the flour and to decrease the amount of free fat that might destabilize the aqueous foam produced during mixing. The box cakes produced are very fine and tender. They are not suitable for commercial production because they are very fragile and would not withstand handling during transport.

16.6.2. Role of Cake Ingredients

The ingredients in batter-type cakes perform specific functions with respect to batter properties and structure, texture and color of the cake.

Bakery Fats/Shortenings, and Surfactants. The fat is used in cake production for batter preparation and structure formation and it is essential for eating properties, flavor delivery, and shelf life of the cake [165]. During batter preparation, the fat causes the incorporation of air and controls, together with the emulsifiers and sugar, batter viscosity. While the solid

(plastic) shortening increases the viscosity during batter preparation, it acts as lubricant decreasing viscosity once it creates a liquid phase during heating in the oven. The viscosity of a cake batter is very important during the baking step. Too low a viscosity will allow large bubbles to rise to the surface and escape. It would also allow starch granules to accumulate at the bottom on the cake pan and produce a rubbery layer during baking.

The introduction of an emulsifying agent (mono- and diacyl glycerols) into a shortening enhances the emulsifying properties of the shortening and hence, complements its use. The batter increases in viscosity, has greater stability, and the air becomes more finely distributed, leading to a larger, moister cake. The batter containing the surfactants maintains a higher viscosity during the early stages of heating. In the later stages of heating, shortenings together with surfactants appear to lower the rate of increase in viscosity by reducing starch swelling. The use of these high-emulsifying fats enables to step up considerably the liquid and sugar level to produce lighter, sweeter, and moister cakes with improved shelf-life.

Sugars. Besides sugar's obvious function as sweetening agent, the amount of sugar in the cake formula affects batter viscosity, starch gelatinization temperature, as well as tenderness and color of the cake. The amount of sugar in the formula controls the onset of starch gelatinization and thereby delays starch swelling. As the level of sugar in the formula increases, the temperature at which starch gelatinizes increases. This mechanism allows more time for the product to rise, resulting in a cake with fine, uniform, porous structure and tender crumb. When the proportion of sugar in the formula is higher than the proportion of flour, the cake produced is called a *high ratio cake*. Due to the high level of sugar the starch gelatinization temperature increases to a point where the cake does not set and thus will collapse during baking. To avoid this phenomenon the flour must be treated with chlorine gas (see Section 5.2). The use of chlorine treated flour allows the use of 120–140 % sugar, based on the flour.

Reducing sugars act as color enhancers and color precursors by taking part in the Maillard browning reaction. Reducing sugars are often added to the formula in the form of milk (lactose) or fresh egg whites (glucose). Sucrose is nonreducing and, because the formula contains no yeast (and therefore no invertase) to hydrolyze sucrose to reducing sugars, it does not give browning. Also because the pH of the system is basic, no chemical hydrolysis of sucrose to glucose and fructose occurs. Therefore, when sucrose is the only sugar in the formula, no browning takes place and the cake is quite white. Invert syrups (a mixture of glucose and fructose obtained by hydrolysis of sucrose) are hygroscopic and used as humectants that increase the retention of moisture in the crumb, resulting in improved eating properties and an extended shelf-life. In addition to the use of sucrose in cake itself, it is an essential ingredient in various icings, toppings and fillings.

Egg Whites. The proteins in egg white increase viscosity at room temperature by facilitating the incorporating of air into the aqueous phase of the batter. During heating, egg white proteins denature, leading to a great increase in batter viscosity and help to set the cake structure. In excess, egg whites tend to produce a tough, rubbery cake texture.

Egg white is the most important component in the angel food cake formula. Generally, the eggs and sugar are whipped to a protein foam, and the flour is folded in carefully so as not to disrupt the foam. The function of the flour appears to be to provide starch that will gelatinize and thereby remove excess free water. A low level of flour, often diluted with wheat starch characterizes the formula. Cream of tartar (monopotassium tartrate) is added to reduce the pH and, thereby, to improve the whipping of the egg whites. The formula contains no leavening agent. Simply the air trapped in the egg white foam produces the leavening. Care must be taken not to introduce any fat into the formula, as fat destabilizes the foam. In fact, one cannot use plastic containers because they retain enough fat to destroy the foam.

Milk, because of the reducing sugar lactose, aids in browning or crust color. It is also generally considered to improve the cakes flavor.

Flour. Cake flours are of low extraction rate, low protein content, and milled to a fine parti-

cle size. Generally, the finer the particle size, the better the cake flour. Therefore, most cake flours are pin-milled to reduce the particle size. Pin-milling also increases the amount of damaged starch in the sample, but this does not appear to affect the cake flour quality. The improvement of flour functionality for cake making by chlorination has been discussed (see Section 5.2).

16.7. Pastries

Pastries can be divided into two product groups: short pastry and puff pastry [210].

16.7.1. Short Pastry

The term short pastry encompasses (1) sweet pastry such as jam tarts, fruit pies, choux paste, (2) unsweetened, savory pastry, and (3) richer pastries such as shortbread and confectioner biscuits. All these products contain significant proportions of fat in the recipe, usually between 40–50 g/100 g flour. The major function of fat is to shorten the texture and to make the product soft and tender so it melts in the mouth. Like in cake production, shortness is achieved by using fats/shortenings that avoid or reduce gluten development. Thus, the elastic gluten strands are shortened and a short paste or pastry dough results. As a tenderizer butter or margarine can be used themselves or in combination with lard, or a general-purpose shortening as the texture of the fat allows its easy distribution throughout the dough.

The high level of sugar in sweetened pastes reduces the availability of water for hydration of the protein and also reduces the tendency for gluten development during paste mixing. Baking powder might be added to short pastes to give a more open texture and a lighter eating product, especially when lower fat levels are used in the pastes since the tendency for gluten development is increased.

16.7.2. Puff Pastry

Puff pastry is a laminated bakery product with a light, flaky texture. It is believed to have originated in France but the art of preparing layered dough was perfected in Vienna, Austria. The puffing, i.e., the volume increase during baking, involves neither chemical or biological leaving but depends solely on the transformation of water to steam that becomes trapped between dough layer separated by thin films of fat resulting from the lamination process [210, 275].

The ability of the roll-in fat to keep dough layers separated primarily determines the quality of puff pastry. Laminating of fat into the dough is achieved by a series of reduction (sheeting) and folding steps that forms alternate and discrete layers of dough and fat. A dough sheet is covered with fat, folded, reduced in thickness by rolling and subjected to further folding and rolling to build up the required number of layers of thin dough sheets with a well developed gluten network separated by layers of fat. As the number of dough and fat layers increases and a multilayer sandwich structure develops, the specific height (mm/g paste) of the baked product first rises to a maximum and then declines. The optimum number of fat layers depends on the type of puff pastry product and the process conditions and should provide a product with a regular structure and flaky texture. Lower levels of layers might give greater specific heights of the final product but a lower quality pastry due to individual layers yielding a fragile, irregular structure with large voids. More laminations eventually result in thinner dough and fat layers causing coalescence of the dough phase and formation of capillaries and micropores through which the steam generated during baking can escape. A distribution of fat through the dough phase with a subsequent disruption of the required gluten network might occur. Both mechanisms, interconnections of the dough phase and interruption of the gluten network would decrease lift and final product volume.

Since the melting of the fat layer destroys the layer, it is imperative that the fat remains solid. Thus, it is a common practice to retard (allow to rest at low temperature) the dough between sheeting operations.

There are essentially three basic production methods for puff pastry (English, French, and Scottish method) that differ in the use of laminating fat. In all cases, the laminated dough is finally cut and formed into the required final shape. If appropriate, the pastry specific height can be controlled by docking of the paste before

baking. Pastry dough can be used for a wide variety of pastries such as baked pastry layers for torte cakes or quiche or as filled products such as Danish pastries, fruit pockets, creme horns, and strudel.

During the initial step of baking the laminating fat melts at 35–40 °C and forms a liquid fat layer. Then, water of the puff pastry dough will evaporate as steam that passes into the molten, liquid fat layer where it inflates large bubbles. The steam moves into the liquid fat because of the smaller pressure differential needed to inflate a bubble of steam in the liquid fat than in the dough phase. The expanding bubbles are trapped between the hardly penetrable multi-layer structure that act as barrier to the water vapor. The pressure generated by the bubbles causes a puffing effect that expands and stretches the elastic gluten network and subsequently leads to the lift. The volume increase of the product during baking may reach up to eight times the original dough volume. The final product structure is fixed by interconnections of dough strands via gelatinization and heat-setting of gluten proteins. All these events are responsible for the well-known open, flaky, and crispy texture of puff pastry.

Only about half of the water vapor generated exerts pressure to lift the pastry. The remaining water escapes as steam after the structure has set and cannot lift the pastry any further. To assure a good lift it, is essential that the integrity of the dough layers is as complete as possible. That means, for lamination until the puffing step the formation of uninterrupted fat separation layers between the dough sheets is required. If dough strands are interconnected the water vapor escapes to the outside through micropores and capillaries. The molten laminating fat partially soaks into the micropores and capillaries of the adjacent dough matrix. This fat acts as filling medium providing lubrication and tender, eating properties.

Ingredients for Puff Pastry Making.

Fat. The fat must give a tough and plastic texture at dough temperature (20 °C). This texture can be reduced to a thin continuous film when subjected to rolling and stretching [276]. This "roll-in-fat" must resist the mechanical stress of the sheeting process and should not be absorbed and penetrate into the dough since this would interfere with the development of the necessary viscoelastic gluten network. The continuous fat film must be a stable barrier separating the adjacent layers of dough, also in the initial stages of baking, to maintain a multi-laminate structure. To avoid an unpleasant waxy or greasy mouthfeel when the product is eaten, there is a limit of using fat with a melting point of ≤ 40 °C. Butter is an excellent roll-in-fat. It contributes to a pleasant taste, aroma, and mouthfeel when processed within a temperature range of 15–20 °C. Special margarines have been developed as roll-in fats. These puff pastry fats used for lamination are made from blends of animal and vegetable fats with high melting points (usually about 40 °C) and high solid to liquid ratios that show little change over a broader temperature range.

Fat also plays a role in puff pastry flavor formation and the type of fat (e.g., butter or shortening) generates different flavor notes. Differences in the concentration of two potent odorants formed during the autoxidation of linoleic acid are most likely the cause for the differences in the overall odors of butter and margarine pastry.

Flour. During lamination, the flour must provide the gluten structure to form a strong dough film that is able to entrap the water vapors as they are formed during baking. This facilitates the formation of large vacuoles to form, leading to a very open texture and large product volume. Therefore, the amount and quality of gluten proteins is essential for the integrity of the paste layers and the lift of the product during baking. Strong flours with protein contents of about 11.5–13.5 %, low extensibility, and high resistance to stretching will yield a better product lift and higher volume puff pastry with a very flaky texture than weaker flours with protein contents < 11 %, high extensibility and low resistance to stretching. Higher protein levels tolerate slightly more lamination, but may not produce a better pastry. The water absorption of the dough is usually 56–62 % of the flour weight. A well-formulated pastry dough has consistency comparable to that of a stiff bread dough and similar to that of roll-in fat during sheeting. Liquid or dried whole eggs not only add liquids to the dough but contribute also to dough strength and to an attractive golden-brown crust color via proteins participating in Maillard browning reactions. Soft doughs are difficult to process and

tend to slide over the roll-in fat during sheeting and the fat will break eventually into lumps that will not form the necessary continuous fat film. The flour specification required also depends on the plant design. After the lamination process the dough is rested for $\geq$ 15 min to allow relaxation of the developed gluten and to avoid shrinkage of the dough during baking. Thus, for short relaxation times weaker flours must be used, for long relaxation times stronger flours.

17. Retention of Baked Product Quality

17.1. Staling

Bread loses its desirability progressively with time it is out of the oven. Those undesirable changes that occur with time are collectively called staling: the crust takes up moisture from the air or the crumb and loses crispness and becomes tough; the crumb becomes inelastic, dry, opaque, firm, and crumbly and loses its coherence; flavor and taste become increasingly stale and off-flavor develops.

The changes that take place in the crust are clearly different from those that occur in the crumb. The toughening of the crust appears to be mainly associated with migration of water from the crumb to the crust [277]. When bread is freshly baked, the crust is dry and only contains 2–5 % moisture. Under these conditions the crust is crisp, friable and desirable. With the time, the moisture migrates to the crust, as an equilibrium is established. At the same time moisture is lost to the atmosphere, so the crust's property is largely preserved. However, if bread is placed in a plastic bag the loss of moisture from the crust is slowed. As a result of this moisture diffusion from crumb to crust, the moisture content of the crust increases. Consequently, the crust loses its friability and becomes tough, the biopolymers (carbohydrates, proteins) forming the crust go through their glass transition temperature and thus, change from a glassy, crispy state to one that is leathery or rubbery (see Chap. 14).

The molecular changes that occur in the bread during storage and that are responsible for the firming and staling phenomenon appear to be quite complex. It was shown about 150 years ago, that the firming of bread crumb is not a drying phenomenon [278]. Firming happens even though no moisture is lost.

In fresh bread crumb, a thin layer of gluten proteins separates swollen, gelatinized starch granules (Fig. 13). Staling of bread involves, among other things, the recrystallization of starch, specifically of the amylopectin fraction (retrogradation, see Section 5.1.1) [50]. Essentially none of the amylopectin becomes soluble during baking. Inside the remnants of the starch granules, amylopectin chains begin to reassociate into ordered structures by forming "junction zones" that consist of double helices. These junction zones serve as nucleation sites for the aggregation of double helices into crystallites (retrogradation). Thereby, a network is formed comprising starch chains passing through amorphous and crystalline regions inside the remnants of the granules. This network appears to contribute to the development of crumb rigidity. The increase in opaqueness of the crumb is presumably caused by the growth of the crystallites, which changes the refractive index.

The concepts of glass transition (see Chap. 14) and the nonequilibrium theory of crystallization (nucleation and propagation: crystal formation, and crystal growth) have been applied to explain the strong influence of the storage time and temperature on starch retrogradation [53, 57]. According to these concepts, the rate of amylopectin recrystallization depends upon the total water content through depression of the T_g and the storage temperature. A bread loaf in the refrigerator has a storage temperature closer to its T_g and the rate of crystal nucleation will be higher. Consequently, if the bread is removed and kept at room temperature, it will stale, i.e., firm faster. The kinetics of the structural changes of the starch in the crumb can be monitored, for example, by changes in the mobility and ordering of the starch chains with NMR, by the development of a β-type pattern ($\rightarrow$ Starch) in the X-ray diffraction pattern, or by the evolution of a melting endotherm at about 55 °C (staling peak) in the DSC (differential scanning calorimetry) profile.

Starch retrogradation has been viewed as the basic cause of bread staling. However, the rate of firming and the rate of starch retrogradation are not the same. In addition, heating can re-

Figure 13. Changes of starch and moisture in bread crumb during storage.

verse the firming of bread crumb. This is one of the advantages of toasting bread; it is said to be refreshened. The retrograded amylopectin crystals melt at about 50 °C, but bread crumb continues to lose firmness as it is heated above 60 °C to about 100 °C. This argues that firming during storage and refreshening during heating is not completely explained by retrogradation of amylopectin.

Apparently, other factors such as water redistribution and starch–gluten interactions are also involved in the staling phenomenon [279, 280]. Cryo-scanning microscopy (Fig. 13), for example, can be used to draw conclusions on the state of water in the bread crumb. Freezable water can be detected by ice crystal formation induced by a slow freezing technique: large crystals indicate high freezable water content, small crystals a low water content. In fresh bread ice crystal formation can be observed in the periphery of the starch granule indicating higher water content at the granule surface than at the granule center. It could therefore be hypothesized that the granule surface is softer, more flexible and easier mechanically deformable than the center enabling a sliding of the starch granule surface over the gluten film. This would result in a softer crumb texture. In freezing stale bread ice crystals increasingly disappear from the inside to the outside of the granule suggesting that water, in part at least, becomes bound within the starch granule as a hydrate, or as nonfreezable water in amylopectin crystals that form upon aging. As a result, granules become more firm. In addition, the moisture gradient between the starch granule surface and the surrounding gluten phase would induce water redistribution from gluten to the starch. This loss of plasticizer (nonfreezable water) could cause adherence of the starch and gluten phase making sliding impossible. This again would contribute to a firming in the crumb texture.

A model for firming has been proposed that includes an effective crosslinking of the contin-

uous gluten phase with the gelatinized starch in bread [280, 281]. This model is based, in part, on the fact that gluten is the continuous phase in bread and that the firmness of bread is a long range phenomenon. Thus, by itself, it would not matter if the discontinuous starch phase is firm or flexible. It is too small to be detected. However, once an interaction between the gluten and the starch has been formed, firming of the remnant of the starch granules would help to firm the total network.

The degree and kinetics of staling of baked goods are affected by several factors such as origin and type of cereal raw material (wheat, rye, extraction rate, wholemeal flour), ingredients (water, fats, sugars, emulsifiers, ethanol), process conditions (baking time, temperature, humidity), product type (bread, buns, rolls, cake, etc), product size, and storage conditions (time, temperature, humidity) [282]. A number of factors alter the rate of staling and produce softer bread that retains its softness over time. A baked product with a high volume and fine crumb structure is softer and retains softness better than a product with lower volume and a coarse crumb grain. Rye breads, in general, stale less fast than wheat breads and baked products made from high extraction flours or wholemeal flours remain longer fresh than products from low extraction flours. Flours produced from partially waxy wheats have shown slower firming rates [22]. The functional properties of waxy wheats and their variation because of environmental and genotypic affect have been reported [283]. The use of fat, sugars, surfactants, and enzymes in the recipe or ethanol sprayed on the surface of baked goods (e.g., cake-type products) can retard staling and retains bread soft. The use of surfactants (emulsifiers) as antistaling additives [172] has been related, among others, to two factors: (1) surfactants form inclusion complexes with amylose and thus, prevent amylose chain association and crystallization [40, 62] and (2) in the presence of surfactants, starch does not swell as much as starch alone. Inclusion of shortening in the bread formula alters the staling rate. In addition, the use of a relatively heat-stable α-amylase in the bread formula retards staling [284] (see Chap. 8). The antifirming effect of these enzymes might be explained by improving loaf volume and crumb structure [175], "softening" the starch network [50], reducing the formation of amylopectin crystallites during storage [185] or by affecting starch–gluten interactions [281]. The conditions at which bread is stored are also important. Higher temperatures retard staling and cooler temperatures (above freezing) increase the rate of firming.

17.2. Microbial Spoilage

Flour contains many microorganisms and most of these are inactivated during baking. Bread and moist fine bakery wares, because of their high water activity and abundant available nutrients are good growth media for microorganisms. If these products are contaminated after baking they can spoil rapidly. One organism that appears to survive baking is the one causing rope. Rope occurs primarily in yeast-leavened products. Rope in bread starts to be noticed as early as 12 h after baking. The bread crumb develops a slightly bitter taste and a fruity odor. With time, the crumb becomes more discolored and the taste becomes repulsive as the bread crumb decomposes. The dark crumb loses its elasticity and can be pulled into fine, silky threads (i.e., rope). At this point the bread is inedible and can cause diarrhea and vomiting.

A baked product is free of fungi as it comes from the oven. However, it can be contaminated during cooling, slicing, or packaging. Mold can develop in about 3 d under ideal conditions. Breads with higher moisture content and thin crusts are more susceptible than those with low moisture and those with a hard, thick crust. Moldy bread has objectionable taste and smell and must be rejected due to safety reasons since the mold-inducing microorganisms may also produce mycotoxins.

17.2.1. Retention of Quality

The trend to larger bakeries and, therefore, transport of baked goods over longer distances has made retention of quality more important. Storage conditions aim at reducing moisture loss, contamination by microorganisms, and enzyme reactions. Recommended storage conditions are 15–20 °C and 65–75 % relative humidity for bread. Both heating and freezing can be used to preserve baked goods. Freezing allows baked

goods to be stored for long periods of time without staling or microbial damage. To reduce staling the product must be frozen and thawed rapidly as storage at just above freezing is subject to rapid firming (see Chap. 14). Freezing can also cause dehydration (freeze drying) of products. Thus, good packaging is important. In general, freezing is expensive. Preservation by heating (45–65 °C, 75–80 % relative humidity) is also quite effective at retarding staling and microbial growth but does have undesirable side effects. Bread with light colored crust might darken and the flavor is affected. Par-baking is also used to preserve baked products such as baguette-type goods, buns, and rolls. Par-baked products are partially baked, packed under modified atmosphere or treated with preservatives and are shelf-stable for some weeks. Fully baked in the consumer's oven they provide fresh baked products. Baked goods are often not packaged if they are expected to be sold and consumed rapidly. For hygiene reasons the goods may be wrapped in paper. Waxed paper does not retain moisture and the product can easily be contaminated with molds. Perforated paper/plastic bags allow moisture transfer from the product to the surrounding air outside of the bag. This mechanism facilitates the moisture evaporation from the product to the air outside and thus, avoids the retransfer of moisture to the crust and helps to keep the crust crispy for a longer period of time. It does not protect against mold contamination. For bread that is sliced and shipped over some distance, polyethylene bags are often used. They can withstand heating to 120 °C retain moisture well, extensible, and flexible. For long term storage (e.g., military use) bread can be baked in cans, which can then be sealed and sterilized.

17.2.2. Chemical Preservatives

The use of chemical preservatives is controlled in various countries by differing rules and regulations. In most countries, various propionates are used to inhibit mold and rope organisms. The most commonly used additive to inhibit mold growth in bread is calcium propionate (0.15–0.30 g/kg). Calcium propionate also retards yeast activity to some extent. Sorbic acid is very effective in stopping mold. However, it also is effective in inhibiting yeast activity. Thus, it cannot be used as a formula ingredient in bread. It is often used in chemically leavened systems or as a spray on the surface of baked products. Ethanol has also been used to preserve baked goods, especially cake-type products.

18. Trends in Baking

18.1. U.S. Bakery Market

Wheat flour per capita consumption in the United States has held steady in 2004–2005 at 60.9 kg. This is at an all-time low. After reaching a modern high of 66.4 kg per person in 2000, the consumption has declined (64.1 kg in 2001 and 62.3 kg in both 2002 and 2003). It appears that the damage done to the milling and baking industries by the "bad carbohydrate" diets persists even though those diets are no longer popular. As one might expect, the above trend has severe effects on the economy of the industry. The large bakers are still closing bakeries and producing more product with fewer plants. This means that the distance between the bakery and the consumer is greater and, therefore, also the time between baking and buying the bread by the consumer is longer.

A trend to high fiber breads continues but the rate of increase has slowed. The high fiber breads include added fiber from such sources as soy hulls, oat hulls, pea fiber, and many others. Whole meal breads also fall in this category. The increased sales of these types appear to be driven by two factors. The first is the perception that whole meal breads are good for the health. The healthy image appears to cover all dark breads. The second trend is based on the fact that the high fiber breads have reduced calorific value. The reduction in calorific value is because the fiber is not completely digestible and because the breads contain high levels of water. Multigrain breads also have a healthy image and sales are growing rapidly compared to other breads.

Bread shops, both free standing in shopping malls and in-store bakeries in supermarkets, continue to grow. Their rapid growth does not appear to be at the expense of the wholesale bakeries. There are, apparently, increased sales of bread which may be, at least partially, responsible for the increase in wheat flour consumption in the USA. Most bread shops sell primarily crusty

breads and most, if not all, of their product is sold within a few hours after being baked. Thus, the costumer has access to fresh bread. Most of the free-standing bread shops also sell sandwiches, salads, and soups in addition to the baked products. Much of the bread produced by in-store bakeries is produced from frozen dough. However, the growth of production of frozen dough appears to have slowed. Frozen dough may be giving up market share to par-baked breads.

A rapid growing product in the United States is the wheat flour tortilla. Sales of tortillas in 2004 were \$ 6.1×10^9 up from \$ 1.1×10^9 in 1997. The trend shows no sign of slowing. The tortilla is the 2nd most popular baked item in the United States after white pan bread. Cookie and cracker markets show little overall growth. The industry appears to be moving away from products that are marketed as "good for you" and concentrating on products with full flavor and things that are fun to eat.

18.2. Western European Bakery Market

European bakeries produce about 25×10^6 t of bread, about 8×10^6 t of which in an industrial environment, and 5×10^6 t of biscuits (cookies in the U.S.), cakes and pastries [285]. Germany is by far the largest producer of bread with a European market share of about 25 %, followed by Italy, France, the UK, and Spain. An average of about 65 kg of bread per capita per year are consumed in Europe with Germany, Denmark, Finland, Italy, and Belgium being the highest in consumption. The Germans and Austrians consume about 80 kg per year while in the United Kingdom and Ireland the annual per capita consumption is below 50 kg.

Bread plays a different role in the diet across Europe. In countries such as Germany and France bread is a major meal component, while in the UK it is seen as an accompaniment to other foods. In addition, different types of bread are favored in different countries. Germany, Norway, Belgium, and the Netherlands tend to prefer brown, wholemeal and mixed wheat/rye bread whereas white bread, mainly baguette, dominates the market in France.

While the bread market is relatively static as a whole there are some sectors where sales are increasing. This includes speciality and ethnic breads such as certain types of flat breads like tortillas, ciabatta, pita and naan bread. A fast growing sector within the bakery market in Europe is the morning goods market (e.g., croissants, rolls, buns, muffins, pancakes, bagels).

The UK, Germany, Italy, and France together contribute to more than 70 % of the total production of the 5×10^6 t of biscuits, cakes, and pastries produced in Europe. Within the biscuit, cake, and pastry sector, biscuits account for about 75 % of the total European production. The UK, Germany, France, and Italy are the greatest consumers of biscuits, cakes, and pastries with about 22 %, 22 %, 16 % and 15 %, respectively, of the total European consumption. In general, the market is stable (average European consumption about 10 kg/a) and is not expected to change dramatically in the future. In contrast to the purchase of bread, the purchase of biscuits, cakes and pastries is more impulse driven. In response, producers across Europe are improving the product appearance (e.g., packaging) and are searching for new merchandising and distribution channels to improve sales.

The production sites of bread and other baked products can be divided into three groups although definitions vary in different countries: (1) craft bakeries that use small-scale machinery and sell their products directly to the consumer, (2) plant bakeries that use large-scale equipment and produce a range of products that is distributed to wholesalers, supermarkets, restaurants etc., and (3) in-store bakeries that are either owned by supermarkets or franchised to a local baker.

Traditional craft bakeries remain dominant in Italy and France while industrial or plant bakeries are more dominant in northern Europe. Overall, plant bakeries are accounting for an increasing proportion (almost a third) of total bread production in Europe. Consolidation and expansion of market positions through mergers and acquisitions has been a noticeable trend. Generic standards for quality and safety management and quality assurance such as ISO registrations and the Hazard Analysis Critical Control Point (HACCP) concept have now been introduced into the bakeries, minimizing food safety issues. Experimental designs, mathematical modeling and knowledge-based expert systems offer new tools in production scheduling,

process control, and baked product development [286, 287].

18.3. Consumer Demands and Product Trends

Convenience, taste and freshness are expected to remain the driving purchases of bakery products [288 – 293]. Dough, batters, and bakery products are widely distributed in frozen, par-baked, and refrigerated form so that they are available at more outlets and can be baked or re-heated on the premises with "just baked" smell and taste. Convenience is essential and baked products whether packaged or just baked are now available at many nontraditional outlets like gas stations. The appeal of freshness is evidenced in the sales of household bread-making machines and the rising popularity of in-store bakeries.

Flatbreads are well suited to trendy sandwiches and flatbread sales are raising. The distinction between snacks and crackers is blurring and some products such as filled bagels make their way into the snack category since they provide a convenient and quick form of energy.

In addition, the concern and interest in a healthier diet will continue to increase and there is a greater demand from consumers to use more nutritional functional ingredients in products [294 – 297]. After the initial phase of curiosity and health-induced purchases, consumers continue to turn away from products like fat-free or low-fat sweet baked good varieties because they are first unhappy with the taste and second nonconvinced about the advertised, claimed, or initially personally perceived health effects of these products. To focus on nutrition, however, will become increasingly important to bakery food producers. In the EU, large research efforts have been launched to provide healthy bread products (see www.solfibred.com and www.healthgrain.org).

Within the health domain, bakery products play an increasingly important role as functional foods, i.e., foods that provide additional physiological effects beyond their traditional effects such as preventing and correcting classical nutritional deficiencies. Bakery products are ideal carriers for bioactive nutrients, since they are produced from cereal grains that contain intrinsically beneficial components and thus, these products can be considered as nutritional functional in nature. The grain components or functional nutrients with favorable properties that can be incorporated in baked products include, among others, dietary fibers/prebiotics like β-glucans, hemicelluloses and fructo-oligosaccharides, resistant starch, phytochemicals, probiotics, antioxidants, vitamins, and minerals [298 – 301].

The increase in health, social and environmental concern of the consumer represents an opportunity for bakers to diversify into good tasting products such as organic multi-grain, fiber/bran enriched breads.

1. Introduction

Bromine, Br [*7726-95-6*], a nonmetallic element of the halogen family, is a dark red-brown liquid at ordinary temperatures and pressures. It appears in group 7 A, period 4 of the periodic table between chlorine and iodine. The name is derived from the Greek $\beta\varrho\tilde{\omega}\mu o\sigma$, meaning stench. It vaporizes readily and has a sharp, penetrating odor. The electronic configuration is: $1s^2$, $2s^2$, $2p^6$, $3s^2$, $3p^6$, $4s^2$, $3d^{10}$, $4p^5$; the most common oxidation states are -1 and +5. Valences of +3, +1, and +7 are also observed.

Bromine was first discovered by A. J. BALARD in 1824. He had isolated the element while studying the flora of a salt marsh near Montpellier, France. He noticed a deposit of sodium sulfate which had crystallized in a pan containing mother liquor from common salt. Investigating uses for the waste liquors, BALARD observed that upon saturation with chlorine, the new red liquid could be obtained by distillation [1]. CARL LÖWIG [2] independently isolated bromine at Kreuznach, Germany, in 1825 and was in the process of studying its properties when BALARD's paper appeared. The first mineral to contain bromine was discovered in 1841 by BERTHIER; the mineral was apparently bromyrite (silver bromide).

The first commercial production of bromine was from native salt brines in 1846 at Freeport, Pennsylvania, by DAVID ALTER. The Dow process for extracting bromine from seawater began in 1934 near Wilmington, North Carolina.

Bromine does not occur in nature as the free element but is found solely as the bromide. There are only a few bromine-containing minerals, all silver ores, among which are bromyrite, AgBr; embolite, Ag(Cl, Br); and iodobromite, Ag(Br, Cl, I). Bromine usually follows chlorine through the geochemical cycle. Crystal rocks contain 2 – 3 ppm bromine.

Bromine also appears in variable amounts in the biosphere. The bromide concentration in terrestrial plants is about 7 ppm and in freshwater plants, 22 ppm. The amounts of bromide found in some edible foods are wheat flour, 19.7 ppm; potatoes, 10.3 ppm; oranges, 3 ppm; and apples, 4 ppm.

In the animal world, the highest bromide contents are found in sea life, such as fish, sponges, and crustaceans [3]. Many natural products containing organic bromine have been isolated, such as dibromoindigo (Tyrian purple) from sea snails, bromoform from red algae, and brominated phenols and diphenyl oxides from sponges and marine bacteria [4]. Animal tissues contain between 1 and 9 ppm bromide and blood bromide ranges between 5 and 15 ppm.

The most easily recoverable bromine occurs in the hydrosphere as soluble bromide salts. The concentration of bromine in seawater is about 65 mg/L. Other sources of extractable bromine occur in salt lakes, salines, and inland seas (Ta-

10.1002/14356007.a04_391

ble 1). The Dead Sea is one of the richest sources, containing nearly 4 g/L of bromide at the surface and up to 6 g/L at deeper levels.

Table 1. Bromine occurrence

	Original content, g/L	After concentration, g/L
Sea water	0.065	
Inland seas		
Kharaghoda, Indian Ocean	0.25	6
Ssassyksee, Black Sea	0.28	1.5 – 4.5
Shebhka el Melah, Tunisia	2.5	6.8
Salt lakes		
Dead Sea, Israel	4 – 6	12 – 13
Ellon Sea, USSR	0.63 – 2.25	
Searles Lake, Calif. (USA)	0.85	
Brine wells		
Michigan, (USA)	2 – 3	
Arkansas, (USA)	4 – 5	
Yakutsk, Siberia, USSR	6 – 7 ($CaCl_2$ solution)	
Mineral salt deposits	wt %	
Rock salt	0.005 – 0.040	
Sylvite	0.117 – 0.300	
Carnallite	0.155 – 0.334	
Bischofit	0.467	
Tachydrite	0.438	
Hard salt	0.05 – 0.20	

The most important source of bromine is brine wells, which is the principal source in the United States. The richest brines are found in Arkansas and Michigan, with bromide content ranging from 2 to 5 g/L. The total bromine content in the crust of the earth has been estimated to be $10^{15} - 10^{16}$ t or 0.00016 % bromine.

2. Physical Properties

Bromine [*7726-95-6*], ^{20}Br, M_r 159.808 (for Br_2), stable isotopes 79 (50.54 %), 81 (49.46 %), is a dense, dark red, fuming, highly corrosive, and lacrimatory liquid. Its strong pungent odor is detectable at 1 ppm by volume in air. The color of bromine varies with temperature (yellow orange at 20 K, orange red, red brown, to almost black at its melting point). Liquid bromine is always dark red, whereas, bromine vapors are usually orange to red brown. The absorption band for liquid bromine lies between 417–420 nm [5].

The physical properties of elemental bromine are summarized in Table 2. The vapor pressure curve is shown in Figure 1.

Figure 1. Vapor pressure curves for Br_2 and water saturated with Br_2
FGJ – JJ′: vapor-pressure curve of Br_2; f (b)k(K′)US – SS′: vapor-pressure curve of Br_2 – containing water; f – K: Br_2 hydrate + ice + vapor; b – K (metastable), k – U (stable): Br_2 hydrate + solution + vapor; k – K′ (metastable): ice + solution + vapor; K′ – U (metastable), U – S, S – S′ (stable): Br_2 + solution + vapor; for S – S′, J – J′ use right-hand axis

The density of liquid bromine (in g/L) in the range 0 – 50 °C can be calculated using the following equation (T is temperature in K):

$$\varrho = 4.1295 - 0.003447T$$

The dynamic viscosity, in Pa · s, can be determined (T is temperature in K):

$$\eta = \left(7.0274 \times 10^{-3}T^2 + 6.037T - 1368\right)^{-1}$$

An important reaction of elemental bromine is its dissociation:

$$Br_2\,(g) \longrightarrow 2\,Br\,(g) \qquad (1)$$

Some data for this reaction are shown in Tables 3 and 4. The free energy (149 640 J at 298.1 K) is calculated using:

$$\Delta F^\circ = 174170 - 10.886T\ln T + 0.0020934T^2 - 20934T^{-1}$$

Table 3. Equilibrium constants for Equation (1)

T, °C	650	800	900	1000
Log K	−5.983	−3.747	−2.854	−2.114

Table 4. Thermodynamic data for molecular and atomic bromine

	ΔH°, J	ΔG°, J	S°, J/K
Br	111788	82480	175.0
$Br_{2\,(g)}$	30564	2931	245.3
$Br_{2\,(l)}$	0	0	152.4

Solubility. Bromine and chlorine are miscible in all proportions, yielding an equilibrium mixture containing the interhalogen bromine chloride:

$$Br_2 + Cl_2 \rightleftharpoons 2\,BrCl \quad K_{eq} = 2.94 \text{ at } 25\,°C$$

This equilibrium mixture can be separated by distillation [10]. The density of bromine – chlorine mixtures (in g/L) can be calculated using the formula:

$$\varrho_T = 4.0916 - 0.0374w_{Cl} - 0.0033T$$

of chlorine in % and T the temperature in K. The solubility of bromine in water is low, 3.5 g/100 g at 20 °C. The solubility curve for bromine in water is represented in Figure 2.

Figure 2. Solubility diagram for $Br_2 - H_2O$ at 101.3 kPa [11]
K′: 4.3 g (−0.58 °C), $Br_{2\,(l)}$ + ice + H_2O; K: 2.27 g (−0.3 °C), Br_2 (hydrate) + ice + H_2O; U: 3.86 g (5.84 °C), Br_2 (hydrate) + $Br_{2\,(l)}$ + H_2O; S: 3.58 g (54.3 °C), *bp*

Bromine forms a red crystalline hydrate, $Br_2 \cdot 8\,H_2O$, which decomposes at 5.8 °C [12]. Bromine hydrate and ice form a eutectic at −6.3 °C. Because of the slow formation of bromine hydrate, bromine in water solution is metastable and forms ice and bromine below −58 °C.

The density of water containing bromine (in g/mL) can be determined using the formula:

$$\varrho_T = 1.0995 + 0.0073w_{Br} - 0.000344T$$

concentration in % and T the temperature in K. Bromine can be recovered quantitatively from a water solution by sparging with air [13]. The solubility of bromine in water can be increased by adding bromide and chloride salts because of polyhalide complex formation (Table 5). Equilibrium constants for the formation of tribromide

Table 5. Solubility of bromine in various aqueous solutions at 25 °C [14], [15]

Solute	c_{solute}, g/L	c_{Br_2}, g/L	Solute	c_{solute}, g/L	c_{Br_2}, g/L

and pentabromide ions at 25 °C have been determined [16]:

$$Br_2 + Br^- \rightleftharpoons Br_3^- \quad K = 16.85$$
$$Br_3^- + Br_2 \rightleftharpoons Br_5^- \quad K = 1.45$$

The relationship between bromine solubility and the concentration of NaBr and KBr salts is shown in Figure 3.

Figure 3. Bromine solubility in salt solutions at 25 °C

The solubility of water in liquid bromine is relatively low (380 ppm at 25 °C, Fig. 4). Commercial bromine usually contains less than 30 ppm water, but bromine has an affinity for moisture and may pick up additional water if improperly handled. For instance, at room temperature, it could reach a water content of 70 ppm if contacted with air at 20 % R.H. This could rise to 300 ppm if the bromine is exposed to air having 80 % R.H., a level that increases considerably bromine's corrosive properties [9].

Figure 4. Solubility of water in bromine

Bromine is miscible with many organic solvents, such as carbon tetrachloride, ether, methanol, alkyl bromides, methylene chloride, chloroform, and acetic acid. Reactions can take place with some of these solvents under certain conditions.

Bromine itself is a good solvent for cesium bromide, as shown in Table 6 along with the solubility of other salts in liquid bromine.

Table 6. Solubility of various salts in liquid bromine, g/100 g solution [8]

LiBr	0.005	$SrBr_2$	0.002
NaBr	0.010	$BaBr_2$	0.005
KBr	0.0185	$NiBr_2$	0.0003
RbBr	0.058	$ZnBr_2$	0.0146
CsBr	19.3	$FeBr_3$	0.324
$MgBr_2$	0.002	$AlBr_3$	0.002
$CaBr_2$	0.003		

3. Chemical Properties

Many chemical reactions of bromine are a result of its strong oxidizing properties. The tendency of bromine to gain a single electron lies as expected between chlorine and iodine, as do most other chemical properties. Bromine is only a moderately strong oxidizing agent (Table 7).

Table 7. Standard potentials of bromine and various other oxidizing agents

I_2 (s) / $2\,I^-$	+ 0.53 V
Br_2 (l) / $2\,Br^-$	+ 1.07 V
Cl_2 (g) / $2\,Cl^-$	+ 1.36 V
F_2 (g) / $2\,F^-$	+ 2.85 V
Fe^{3+}/Fe^{2+}	+ 0.77 V
Ce^{4+}/Ce^{3+}	+ 1.44 V
MnO_4/Mn^{2+}	+ 1.52 V
Pb^{4+}/Pb^{2+}	+ 1.8 V

Corresponding to its position in the electromotive series, chlorine oxidizes bromide ion to elemental bromine. This reaction is the chemical basis for the production of bromine (see Chap. 4).

Of the bromine fluoride compounds (BrF, BrF_3, BrF_5), BrF_3 is of greatest practical importance because of its use in fluorinating organic substances.

Bromine undergoes *reduction* to bromide in water. The reducing agent can be either the water itself or the remaining bromine. In the first case, oxygen is formed:

$$2\,Br_2 + 2\,H_2O \longrightarrow 4\,H^+ + 4\,Br^- + O_2 \quad E^\circ_{298} = +0.25\,V$$

The potential for corresponding reactions is + 2.055 V for fluorine, + 0.544 V for chlorine,

and -0.28 V for iodine. Thus, bromine reacts less vigorously with water than fluorine and chlorine.

When bromine itself becomes the reducing agent, bromide and hypobromite are formed:

$$Br_2 + H_2O \longrightarrow H^+ + Br^- + HOBr \quad E^\circ_{298} = +0.525\ V$$

The equilibrium constant for this reaction is 5.8×10^{-9} at 25 °C and varies little with temperature [17]. This reaction can be suppressed by addition of acid. With a small amount of base, the reaction goes to completion. In strong base, the reaction occurs only in the cold. Warming under these conditions converts the hypobromite to bromate and bromide:

$$3\,NaOBr \longrightarrow NaBrO_3 + 2\,NaBr$$

With the addition of acid to the bromate–bromide mixture, bromine is again formed.

Ammonia is oxidized by bromine to nitrogen:

$$3\,Br_2 + 8\,NH_3 \longrightarrow 6\,NH_4Br + N_2 \quad \Delta H = -879.2\,kJ\ [18]$$

Bromine reacts with *hydrogen cyanide* to give cyanogen bromide:

$$Br_2 + HCN \longrightarrow BrCN + HBr$$

Carbonates react similarly to alkali, forming the bromide and bromate salts:

$$3\,Na_2CO_3 + 3\,Br_2 \longrightarrow 5\,NaBr + NaBrO_3 + 3\,CO_2$$

Sulfur dioxide is oxidized to sulfuric acid by bromine:

$$SO_2 + Br_2 + H_2O \longrightarrow 2\,HBr + H_2SO_4$$

The latter two reactions are used commercially in recovering or neutralizing bromine residues.

Bromine reacts with many *metals* to form bromides. Sodium is stable in dry bromine, but sodium vapor reacts vigorously. Potassium and cesium react violently with bromine. Bromine is also highly reactive with aluminum and titanium. Aluminum reacts with emission of light. Magnesium, silver, nickel, and lead become coated with their bromide, which prevents further reaction. This protective coating makes lead a useful material for containers of bromine. Other nonferrous metals, that are useful in handling bromine are nickel, tantalum, Hastelloy C, and monel and certain other copper alloys.

Moisture is important in the corrosion of metals by bromine. This is probably due to the hydrolysis products, hydrobromic and hypobromous acids. At moisture contents below 40 ppm, nickel containers can be used for transporting bromine [19]. Mercury is attacked by bromine and should not be used in instruments and gages exposed to bromine vapor. Dry bromine reacts slowly with iron to form a protective layer of ferric bromide; but when wet, a mixture of hydrated iron bromides is formed which does not adhere to the iron surface [20]. Other heavy metals, such as copper, manganese, chromium, antimony, cobalt, cadmium, and bismuth, react with bromine, although some metals require higher temperature.

Bromine also reacts with plutonium and uranium and offers the possible separation of UBr_4 and $PuBr_3$ by distillation. Titanium and zirconium are said to form H_2TiBr_6 and H_2ZrBr_6 in solution [21].

3.1. Bromine Addition to Alkenes and Alkynes

Bromine adds readily to unsaturated compounds. Such reactions are usually run at low temperature to avoid substitution side reactions. Although a catalyst is usually not required, ultraviolet radiation or high temperature may be used to accelerate the reaction.

Among the more important commercial products from bromine addition to unsaturated compounds are ethylene bromide, acetylene tetrabromide, 2,3-dibromopropanol, and hexabromocyclodecane. Ethylene bromide is the largest volume bromine-containing organic chemical produced (→ Bromine Compounds, Chap. 1.4.1.).

3.2. Bromination of Aromatic Compounds

Aromatic compounds can undergo three types of reactions with bromine: (1) addition, (2) substitution on side chains, and (3) substitution on the aromatic ring.

The light-catalyzed addition of bromine across aromatic double bonds is generally a slow

reaction, but use of chlorine increases the rate. Bromination of aromatic side chains is normally a free-radical process.

Electrophilic substitution on the aromatic ring is by far the most important type of aromatic bromination. In the presence of a catalyst, bromine reacts with aromatic compounds to give aryl bromides and hydrogen bromide:

$$ArH + Br_2 \longrightarrow ArBr + HBr$$

Suitable catalysts for aromatic brominations are Lewis acids, such as halides of aluminum, iron, zinc, or antimony. Activated aromatic compounds, such as phenols, anilines, and aromatic ethers, can be brominated without a catalyst. Bromine is more efficiently used in aromatic substitution reactions in situ generation of it from hydrogen bromide using chlorine:

$$2\,ArH + Br_2 + Cl_2 \longrightarrow 2\,ArBr + 2\,HCl$$

Preformed bromine chloride can also be used for the same purpose. Substitution reactions involving BrCl are much faster than ones using bromine alone [22].

3.3. Free-Radical Bromination

Bromination of saturated hydrocarbons and of alkyl side chains of aromatic compounds occurs by a free-radical chain reaction:

$$Br_2 \longrightarrow 2\,Br\cdot$$
$$RH + Br\cdot \longrightarrow R\cdot + HBr$$
$$R\cdot + Br_2 \longrightarrow RBr + Br\cdot$$

Dissociation of bromine molecules is needed to initiate this reaction. Bromine can be dissociated thermally, photolytically, by gamma radiation, or by use of peroxide initiators. Compared with chlorine, the bromine atom is less reactive and the hydrogen abstraction step is endothermic. As a result, reaction rates are relatively slow and the bromine atom exhibits high position selectivity. For example, in bromination of *n*-butane, secondary hydrogen atoms are replaced 82 times faster than primary ones [23]. Bromination of aromatic side chains is a much faster reaction than bromination of alkanes.

3.4. Production of Hydrogen Bromide

Hydrogen bromide [*10035-10-6*] is an important intermediate in producing various organic and inorganic bromides (→ Bromine Compounds). It is prepared commercially by the direct gas-phase reaction of hydrogen and bromine:

$$H_2 + Br_2 \longrightarrow 2\,HBr + \text{heat}$$

The reaction can be conducted without catalyst by maintaining a self-sustaining flame within an enclosed burner [24].

3.5. Bromination Using Bromine Carriers

Bromine complexes and bromoimides are useful for brominations where selectivity is of prime importance. The bromine carrier that has found the most use in laboratory brominations is *N*-bromosuccinimide (NBS) [*128-08-5*]. A unique application of NBS is in free-radical allylic brominations:

$$CH_2{=}CHCH_3 \xrightarrow{NBS} CH_2{=}CHCH_2Br$$

Other useful bromine carriers are dibromodimethylhydantoin, dioxane dibromide, pyridine hydrobromide dibromide, and various quaternary ammonium polybromides [25].

4. Production

Bromine production utilizes bromine-containing liquors (brines), which occur naturally, or result from the manufacture of potassium salts or from seawater.

In most brines, as well as in ocean water, the molar concentration of chloride ions is likely to be 200 to 700 times as large as that of bromide ions. Therefore, isolating bromine from these sources requires a separation method of high selectivity. Fortunately, such a method exists. It is based on the greater ease with which bromide can be oxidized compared to chloride, and the fact that the oxidation product, bromine, is quite volatile. Chlorine [*7782-50-5*] serves as the most economical and convenient oxidant. The normal

oxidation – reduction potentials ($E°$) applicable to the operation are:

$$1/2\,Br_2 + e^- \longrightarrow Br^- \quad E° = +1.09\,V$$
$$1/2\,Cl_2 + e^- \longrightarrow Cl^- \quad E° = +1.36\,V$$

Two general processes using chlorination for bromine recovery are based on this chemistry:

1) Steaming-out process for brines and waste liquors containing bromine
2) Blowing-out process for seawater.

4.1. Steaming-Out Process

Production of bromine from brines containing Br^- in concentrations of 1 – 5 g/L basically follows the process described by KUBIERSCHKY in 1906 [26].

Raw brine is warmed in a heat exchanger (a) and caused to pass successively through two packed towers (b), (c) by gravity flow (Fig. 5). In the upper (smaller) tower, it meets a recycle stream of gases from which chlorine and bromine are absorbed. Near the bottom of the lower tower (c), chlorine and steam are introduced; as they pass upward, the chlorine reacts with bromide in the brine, and a mixture of bromine vapor and chlorine (about 85:15 by weight) with steam is taken off the top. The water and most of the halogens are condensed (d), the liquid phases enters a gravity separator (e) and the gas goes to the upper tower. From the separator, water containing dissolved halogens is sent to the lower (steaming-out) tower and the heavier bromine layer, containing some chlorine, flows to a fractionating column (g). The chlorine vapors join the stream to the upper tower while the liquid bromine, about 99 % pure, is drawn off either for direct use in the manufacture of bromine compounds or to be further purified for sale or for more exacting uses.

The hot debrominated brine is treated to neutralize acidity (h) and to reduce free halogens, if necessary, and then is passed through the heat exchanger, where it warms the incoming brine.

More recent modifications of the original Kubierschky process are related generally to the larger scale of modern operations, to the materials of construction, which must be corrosion resistant, and to the procedures and instrumentation needed for control. Whereas originally most of the construction was stoneware, brick, or lead, now much of the material exposed to wet halogens is glass, tile, or other special ceramics or al-

Figure 5. Bromine steaming-out process
a) Bromine cross heat exchanger; b) Chlorine absorber; c) Steaming-out tower; d) Condenser; e) Separator; f) Stripping column; g) Fractionating column; h) Neutralizer

loys; tantalum may be used for condensers [27]. The processes are controlled by measuring pH, oxidation – reduction potentials, flow rates, temperatures, and pressures at critical points.

Some acidity is generated when chlorine reacts with reducing substances, such as hydrogen sulfide, in the brine. This acidity adds to the efficiency of bromine liberation by preventing hydrolysis to hypobromous acid. Use of sulfuric acid is not advisable if the brine contains calcium or strontium because they may precipitate as sulfates and foul the tower packing, heat-exchange surfaces, or brine disposal wells. However, sulfates will form if the brine contains sulfides.

4.2. Seawater Process

The first economically successful recovery of bromine directly from the sea was carried out near Wilmington, North Carolina (USA), using an *air-blowing process* originally developed for brine operations by H. H. Dow [28]. The use of air rather than steam is necessary because the cost of steam to heat ocean water, with its bromine content of only about 65 mg/L, would be prohibitive. The Wilmington plant has since been abandoned, but the process is 1986 still employed, e.g., at Amlwich (Wales) and Hayle (Cornwall).

Water from the ocean is pumped to the top of blowing-out towers, with sulfuric acid and chlorine being added just above the pumps so that mixing takes place during the ascent. About 1.3 kg of 10 % sulfuric acid per ton of water is required to neutralize the natural hydrogen carbonates and bring the pH to 3.5; 15 % excess chlorine over the theoretical requirement is used [29].

Air is drawn up through the towers, sweeping out a mixture of bromine and chlorine (or bromine chloride) from the descending ocean water. The air is drawn next through absorber towers in which it is scrubbed counter-currently by sodium carbonate solution. The several reactions which take place may be summarized approximately by the equation:

$$3\,Na_2CO_3 + 2\,Br_2 + BrCl \longrightarrow NaBrO_3 + 4\,NaBr + NaCl + 3\,CO_2$$

To remove spray from the air, small packed chambers are interposed between the absorber towers and the fans. When the alkalinity of the scrubber solution is nearly depleted, the solution is brought first to a storage tank and then to a reactor in which it is treated with sulfuric acid and steamed to release bromine:

$$NaBrO_3 + 5\,NaBr + 3\,H_2SO_4 \longrightarrow 3\,Br_2 + 3\,Na_2SO_4 + 3\,H_2O$$

The bromine is condensed and used in the manufacture of ethylene dibromide.

In a modification of the process [30], [31], which was used for a number of years at Freeport, Texas, halogens blown from the ocean water are reduced with sulfur dioxide and absorbed in a water spray:

$$Br_2 + SO_2 + 2\,H_2O \longrightarrow 2\,HBr + H_2SO_4$$
$$BrCl + SO_2 + 2\,H_2O \longrightarrow HBr + HCl + H_2SO_4$$

The resulting aqueous solution of mixed acids is treated with chlorine in a conventional steam-out tower and the bromine is recovered. The mixture of hydrochloric and sulfuric acid remaining is used for acidifying the raw ocean water.

The *SO_2 process* has been described [32]; further details of its operation at Freeport and the automatic controls employed there are available [33]. Normal flow of incoming gulf water is 568 m^3/min; the rubber-lined riser pipe is about 12 m tall and 2.1 m in diameter. A glass electrode at the top of the riser measures the pH to within 0.02 unit and controls "butterfly" valves in a return line on the acid supply pumps. Oxidation potential is controlled at about 970 mV with a platinum electrode and a saturated calomel reference electrode, regulating the addition of chlorine. Oxidation potential measurements are also used to control the mixing of sulfur dioxide with the free halogen vapor stream and the chlorination of the reduced acid mixture.

Analytical methods used for bromide in brines and ocean water have been described [34]. Usually the van der Meulen method [35] or one of its various modifications is employed. *Economic factors* important in the location of seawater bromine plants, especially as they were related to the siting of the Amlwich operation, have been discussed [36]; temperature of the water has a significant effect on the efficiency of the blowing-out process [32].

Because of the large volume of ocean water processed, the bromine-depleted stream must

be discharged at some distance from the intake and in a favorable location from the standpoint of prevailing currents, to avoid dilution. Aside from this, *waste disposal* is not a problem since both the acidity and the free halogen content of the outgoing water are very low. In contrast, the waste stream from a strong brine process requires neutralization and, in some instances, reduction. In most cases, spent well brine is returned to the ground via disposal wells to maintain hydrostatic pressure within the formation. Acidity or free halogens should be absent to minimize corrosion of the system. Lime or caustic soda are customarily used for neutralizing acidity. The use of semiburnt dolomite with sodium thiosulfate has been recommended [37].

4.3. Electrolysis

Electrolysis was used in early production in Germany instead of chlorine to oxidize bromides. Two processes were developed in Germany. The *Wunsche electrochemical process* was based on the use of diaphragms to provide good current efficiency. The carbon cathodes were separated from the carbon anodes by porous clay cylinders, which allowed ion diffusion. The anode reaction product was bromine:

$$2\,Br^- \longrightarrow Br_2 + 2\,e^-$$

The cathode reaction produced hydrogen and magnesium hydroxide, which created a major problem of clogging the clay diaphragm pores:

$$Mg^{2+} + 2\,e^- + 2\,H_2O \rightarrow Mg(OH)_2 + H_2$$

The *Kossuth electrochemical process* used bipolar carbon plate electrodes with one side serving as anode and the other side as cathode. The power supply was connected to the end electrodes, and to dislodge the magnesium hydroxide deposits that built up on the cathodes, the current was periodically reversed for a short time. Despite this advantage over the Wunsche process, the Kossuth process had very low-current efficiency. The amount of power required related to bromine was 3000 kW h/t as compared to about 2000 kW h required to produce 500 – 600 kg of liquefied chlorine used to make 1 t of bromine by the Kubierschky process (Section 4.1.), which was being developed at the same time.

Another process for the recovery of bromine from seawater was developed on a commercial scale by Ethyl Corp. in the United States. The process involved the treatment of seawater with chlorine and aniline, and collection of the precipitated tribromoaniline. The company later used a 4200-t ship as a floating factory, which was unsuccessful.

Current bromine production methods are based on modified Kubierschky or steaming-out processes and Dow Chemical's blowing-out process.

4.4. Bromine from Recycle and Waste Brines

In the United States, a modified Kubierschky process has been used for recovering bromine as a byproduct from potassium chloride production liquors at Searles Lake [38]. The Searles Lake brine contains ca. 0.085 % bromine, but it is too alkaline and too heavily buffered for direct use in the conventional chlorine process of liberating bromine. However, since potassium bromide and potassium chloride are isomorphous, the bromide crystallizes with the potassium chloride. This mixture, containing up to 1.8 % bromide, is neutral and therefore useable. When chlorinating this mixture, the bromine is expelled and recovered while an equivalent amount of new potassium chloride replaces the bromide and thus effects the desired purification of the chloride product.

For economic reasons, increasing attention is being given to the development of methods for recovering bromine from byproduct bromides, such as those obtained in halogen displacement reactions. Many substitution reactions produce a kilogram of bromine in the form of byproduct hydrogen bromide for each kilogram of bromine substituted in the desired product. The hydrogen bromide, which is usually released as a gas, is absorbed in water or in an alkaline solution using a scrubber. The aqueous scrubber effluent is acidified and chlorinated in order to recover the bromine for recycle. In some cases, the hydrogen bromide is recovered and used as is or as the bromide salt in other applications.

4.5. Purification

Bromine produced by either the steaming or blowing processes ordinarily contains as impurities chlorine, water, halogenated hydrocarbons, and acids (HCl or HBr). Fractional distillation brings the purity to 99.5 – 99.7 %, long associated with commercial bromine. Improvement to the 99.9+ quality available at present may be done by proprietary methods, of which the following may be considered representative.

Maintaining bromine at 50 °C for 4 h with provision for removal of the vapor lowers the chlorine content from 0.12 to 0.06 % and moisture from 0.05 to 0.005 % [39]. Passing predried, vaporized bromine and oxygen through a tube packed with quartz or Vycor glass fragments and heating to 1000 °C decomposes organic halogen compounds, such as chloroform [40]. Heating bromine vapor to 370 – 540 °C decomposes organic impurities to HCl and to higher boiling compounds which can be removed by distillation [41]. A mixture of steam and bromine can be heated to similar temperatures. Upon cooling, the impurities remain largely in the aqueous phase [42]. Absorption of bromine by a bromide solution with subsequent steam stripping provides highly purified bromine with essentially no chlorine [43].

To avoid corrosion of lead, nickel, or monel containers, less than 30 ppm water should be present in bromine. Drying with concentrated sulfuric acid removes most of the moisture. Organic impurities can be removed by distilling bromine at 58 °C with 96 % sulfuric acid, ca. 2 L/1000 kg, washing the condensed bromine with water, and drying countercurrently with 98 % acid [44]. In addition drying can be done with molecular sieves, type 3 A – 5 A (0.3 – 0.5 nm) [45]. The laboratory preparation of extremely pure bromine for physical properties determination has been described [46].

5. Quality Specifications and Testing

Typical industrial product specifications for purified bromine are [47]:

Bromine, min.	99.98 %
Chlorine, max.	100 ppm
Water, max.	30 ppm
Nonvolatile residue, max.	30 ppm
Organics, total identifiable, max.	100 ppm

Bromine and bromine compounds can be analyzed by the following methods [48]. Liquid bromine and bromine solutions can be assayed by standard iodometric titration [49]. Bromine vapor can be analyzed by absorption in aqueous potassium iodide solution and the liberated iodine titrated iodometrically. A modification of this procedure uses a spectrophotometer to measure the iodine concentration by determining the absorption of the triiodide ion formed by addition of excess iodide [50].

A method for the separation of iodide, bromide, and chloride ions in any mixture involves selective oxidation and distillation, followed by potentiometric or spectrophotometric determination. Other methods for analyzing mixtures of halide ions include chromatography and precipitation.

Various procedures are used for the analysis of impurities in bromine. For example, chlorine content (η) in bromine can be calculated (in wt %) by accurately measuring its density (ϱ) and then using the formula:

$$\eta = 109.4 - 0.088234T - 26.738\varrho$$

A more accurate and convenient method for chlorine determination is ion chromatography [51]. Pure bromine is transparent in the infrared, so water and organic impurities can be measured by their IR absorption spectrum. The residue after evaporation of bromine is determined by heating a sample in a tared container on a steam bath, drying at 105 °C, and weighing.

The bromine content in organic compounds can be determined by neutron activation and X-ray fluorescence.

6. Storage and Transportation

Bromine is usually shipped in monel alloy drums constructed of 14-gage metal and designed to contain 38 L or 102 kg of liquid bromine. Larger bulk shipments of bromine use lead- or nickel-lined tank cars or tank trucks. The latter must be filled to a minimum 98 % of capacity before shipping to avoid inertia effects in transport.

The relatively high freezing point of bromine (−7.25 °C) may cause some problems in storage and shipping. If there is evidence that the bromine is frozen, although the cars are

usually insulated, warm water (below 54 °C) should be circulated through the heating coils. Steam should never be used, as bromine boils at 58.6 °C.

Storage tanks should be protected from moist air. Bromine that contains 30 ppm of water will pick up moisture from air having a dew point of −70 °C. Bromine in equilibrium with air having a normal summer dew point of 5 – 10 °C contains about 70 ppm of water. Corrosion of many bromine-handling metals is severe at this concentration of water. To keep out moisture, a very slight positive pressure (25 Pa) should be kept on bromine storage tanks by purging dry nitrogen or dry air into the tank vent line just above its connection to the tank. When pressurization of the tank is necessary for unloading, dry air should be used, and no more pressure applied than is required to lift the bromine to the highest point in the unloading system (7 kPa gage pressure lifts bromine 0.23 m).

For transferring bromine, plastic-lined steel is a versatile material that combines chemical resistance with reinforced strength. Fluorinated plastics, such as Kynar, Teflon, Kel-F, and Viton, find widespread use in equipment, valves, piping, and gaskets. Nickel, monel alloys, and Hastelloy C alloys may be used with dry bromine (less than 30 ppm water) but are severely attacked by wet bromine. Tantalum may be used with either wet or dry bromine up to 150 °C. Steel and stainless steel usually are unsatisfactory. However, the use of steel is possible when nitric oxide are present to prevent corrosion. Chemical lead- and glass-lined steel are probably the most versatile and practical materials for general use in storing and handling bromine. For additional information, see industrial product brochures on bromine handling and shipping [9].

7. Uses

The primary use for elemental bromine is in the manufacture of bromine compounds that have chemical and biological activity, high density, or fire retarding and extinguishing properties. Bromine products are well represented in such use areas as gasoline additives, flame retardants, agricultural chemicals, drilling fluids, photographic chemicals, sanitizers, dyes, pharmaceuticals, and others.

The largest use of bromine is as ethylene dibromide (EDB), a lead scavenger additive used in gasoline with tetraalkyllead compounds to reduce engine knocking. In the past 10 years, the EDB share of the United States bromine market dropped from 70 % to under 30 %, which can be attributed partly to government regulations issued in 1973, gradually reducing the lead content in gasoline. The use of EDB as a fumigant in agriculture is also on the decline for environmental reasons.

The high-density characteristics of bromine compounds are advantageously applied in hydraulic fluids, gage fluids, ore flotation, and drilling fluids. Calcium bromide, 53 % in aqueous solution, was introduced in 1972 as a dense fluid product (1.70 kg/L) for use as oil well packs and completion fluids [52]. The use of calcium bromide, zinc bromide, and sodium bromide as completion fluids in oil and gas well drilling grew rapidly in the 1970s, capturing 22 % of the elemental bromine market [53].

Another of the fastest growing uses for bromine is in the manufacture of flame retardants (→ Flame Retardants). Bromine fire retardants are benefiting from increased use of engineering plastics and hold an estimated 16 % of the elemental bromine market. Some of the major bromine products used as flame retardants are tetrabromobisphenol A, decabromodiphenyl oxide, and vinyl bromide.

Bromine is also used, either directly or indirectly, in sanitary preparations, water disinfection, in the desizing of cotton, in bleaching of pulp and paper, air conditioning absorption fluids, and hair waving compositions.

8. Economic Aspects

World bromine production for 1993 was reported to be about 3.73×10^5 t. The distribution for each major producing country is shown in Table 8.

Table 8. World bromine production

Country	$\times 10^3$ t			
	1982	1983 *	1984	1993
United States	181.9	172.4	153.0	163.0
Israel	69.9	69.9	99.0	135.0
Former States of USSR	68.0	68.0	68.0	19.0
United Kingdom	27.0	22.7	27.0	–
France	15.9	13.6	9.0	15.0
Japan	12.0	11.8	11.7	–
Federal Republic of Germany	4.0	3.6	3.2	–
Italy	0.6	0.5	0.4	–
Spain	0.4	0.4	0.4	–
India	0.4	0.4	0.4	–
Other countries	0.9	0.9	0.9	–
Total	381	364.2	373	366

* Production was down due to economic recession

9. Toxicology and Occupational Health

In the vapor state, bromine is similar to chlorine in physiological reactions. As a result of its oxidizing action, comparatively low concentrations of bromine vapor are highly irritating to the entire respiratory tract, the mucous membranes, and the eyes, producing responses, such as coughing and smarting of the eyes. The approximate exposure limits for bromine are given in Table 9.

Table 9. Exposure limits for Br_2 vapors [54–56]

	Vapor concentration, ppm
Maximum allowable concentration that is tolerated without disturbance	
prolonged exposure (several h)	0.1 – 1
short exposure (1/2 – 1 h)	4
Least detectable odor	≈3.5
Least amount causing irritation to the throat	15
Dangerous to life (short exposure)	40 – 60
Rapidly fatal on very short exposure (< 30 min)	1000
TLV: TWA	0.1 (0.7 mg/m^3)
STEL	0.3 (2 mg/m^3)
MAK	0.1 (0.7 mg/m^3)

Exposure to high concentrations of Br_2 vapor leads to inflammation and congestion of the respiratory system and edema of the lungs, which in severe cases can be fatal. The sharp odor of bromine gives warning against acutely dangerous exposure but not against concentrations which may be harmful as a result of prolonged exposure.

Liquid bromine presents a serious hazard in handling. It rapidly attacks the skin and other tissues to produce irritation and necrosis; the burns are not only painful but slow to heal. Liquid bromine can also cause severe eye damage.

For the average person, the ratio of bromine to chlorine is roughly about 1:100 in both blood and urine. Table salt has been implicated as the major source of dietary bromine, as it may contain as much as 0.1 % (1000 ppm) bromide [57]. The World Health Organization in 1967 stated that the maximum acceptable daily intake of bromide ion is to be 1.0 mg/kg.

Acute bromide intoxication is rare because amounts sufficient to elevate the serum bromide to a toxic level can hardly be ingested and retained without vomiting. Chronic bromide intoxication from the continued use of large doses (> 3 – 5 g/d) is known as bromism. The symptoms are skin rash, glandular excretions, gastrointestinal disturbances, and neurological disturbances. Bromide compounds have been used in the treatment of neurological disturbances as a sedative and in the control of epilepsy at doses of 3 – 5 g/d [58].

Dilute aqueous solutions of bromine exert considerable germicidal action; comparable studies suggest that it is commonly between chlorine and iodine in its activity against bacterial spores, although with some species, e.g., yeast and certain algae, it appears to be more toxic than chlorine. During disinfection, when ammonia compounds are present, the bromine (bromamine) species are much more toxic to

microorganisms than are chlorine (chloramine) species [59]. Also, the lower stability of bromamine residuals lowers their potential hazard to marine life by discharged effluents. In specific cases, the toxic action of bromine may well depend upon oxidation of enzyme functional groups, such as −SH and −SS−, or of the protein coat of the organism.

Safety Precautions. Safe handling of bromine demands the following measures: (1) rigorous avoidance of all contact of bromine with skin, eyes, and clothing, and (2) adequate ventilation with all possible precautions against inhaling the vapors when significant quantities of bromine are to be handled. Good practice requires that goggles, face shield, gloves, and plastic or rubber suit be worn and that suitable gas masks be available. Preventative health measures and first-aid procedures are given elsewhere [9].

In the case of a bromine spill, all unprotected personnel should be evacuated from the area contaminated either by liquid or by vapor releases. Containment of the spill should be given first priority. Liquid bromine can be contained using earth, sand, or inert material. Vapors can be contained by covering the spill with water. Bromine can then be neutralized or decontaminated with potassium carbonate solution (10 – 50 %), sodium carbonate, hydrogencarbonate, or sodium thiosulfate (hypo). Anhydrous ammonia (in cylinders) is useful for neutralizing any bromine fumes. It is also useful in locating bromine leaks.

1. Organic Bromine Compounds

In almost all of its properties, both physical and chemical, bromine is intermediate between the other active halogens, chlorine and iodine (→ Bromine). These same intermediate characteristics are also found in organic compounds in which halogen is covalently bonded to carbon (→ Chlorine, → Chlorinated Hydrocarbons, → Iodine and Iodine Compounds). In general the organic compounds of bromine tend to be less stable and more reactive than the corresponding chlorine compounds, but more stable and less reactive than their iodine counterparts. Because of their unique physical, chemical, and biological properties, organic bromides have found wide use in numerous commercial products and industrial applications.

Annual production of organic bromine compounds is also intermediate between that of the organic compounds of chlorine and iodine, mainly because of the cost of the elemental halogens. On a mass basis the relative costs of chlorine, bromine, and iodine are about 1 : 4 : 78, but on a molar basis these relative costs rise to about 1 : 9 : 280, respectively. In spite of apparent economic disadvantages, the unique properties and greater reactivity of organic bromine compounds compared to their chlorine analogs are sufficient in many cases to justify the higher cost of bromine. Furthermore, recycle of byproduct inorganic bromides to bromine can almost eliminate the premium cost of bromine over chlorine.

In terms of bromine consumption, organic compounds accounted for about 75 – 80 % of elemental bromine production, and inorganic

10.1002/14356007.a04_405

compounds accounted for the remainder in the early 1980s. Ethylene dibromide, largely because of its use as an additive for leaded gasoline, is still the largest volume organic bromine compound produced. Organic bromides are used in many other applications, such as flame retardants, chemicals for agriculture and water treatment, pharmaceuticals, disinfectants, flame extinguishing agents, and dyes. Bromine and its organic compounds are also widely employed as chemical intermediates for the production of other commercial organic compounds.

The scope of this article is limited to those organic bromides having industrial significance. General reference works should be consulted for the numerous other small-volume applications in industry and in basic and applied chemistry [1–6].

1.1. Physical Properties

Except for the gaseous lower aliphatic bromides, organic bromides are either liquids or solids at ambient temperature and pressure. In general the boiling points fall between those of the corresponding chlorine and iodine compounds, as do the melting points, relative densities, and refractive indexes. Simple organic compounds containing bromine are generally soluble in most common aliphatic and aromatic solvents, such that some bromine compounds are classified as solvents. On the other hand their water solubility is usually low and is roughly inversely proportional to their relative molecular mass [7].

Because many organic bromine compounds have been known for years, their physical properties have been documented [8]. Their spectroscopic and electronic properties, in conjunction with their chemical analysis, are discussed in general texts [9], [10]. Representative lists of aliphatic and aromatic bromine compounds and their physical properties are given in Tables 1 and 2, respectively.

1.2. Chemical Properties

The chemistry of organic bromine compounds is so extensive and varied that only a few of the reactions used in the chemical and related industries are briefly discussed. In general, organic bromides undergo these displacement and other chemical reactions with greater facility and usually in higher yield than the less expensive organic chlorides. This comparative advantage, coupled with their more efficient preparation, accounts for much of their industrial importance.

1.2.1. Nucleophilic Displacement of Bromine

Bromine bonded to tetravalent carbon is a good leaving group and is readily displaced by neutral or anionic nucleophiles to form a wide variety of other useful organic derivatives. Aliphatic bromides undergo these substitution reactions by either unimolecular (S_N1) or bimolecular (S_N2) reaction mechanisms that may be accompanied by competing elimination reactions (E 1 or E 2). The rates of substitution or elimination are influenced by a number of factors, such as the substrate structure, the presence of neighboring groups, the nature of the solvent, and the concentration of reactants, to cite a few. Appropriate reaction conditions can usually be chosen so that either substitution or elimination reactions will predominate:

$$RCH_2CH_2Br + Nuc^- \begin{cases} \rightarrow RCH_2CH_2Nuc + Br^- \ (S_N1 \text{ or } S_N2) \\ \rightarrow RCH{=}CH_2 + NucH + Br^- \ (E1 \text{ or } E2) \end{cases}$$

where Nuc^- is any nucleophile. In general, aryl and vinyl bromides undergo these reactions only with difficulty, although there are exceptions. Some examples of the many nucleophiles used to displace bromine in commercial processes are water, secondary and tertiary amines, cyanide and phenoxide ions, the carbanions of active methylene compounds, and trisubstituted phosphines and phosphites.

1.2.2. Displacement of Bromine by Metals

Both aliphatic and aromatic bromides can react with magnesium to form alkyl- and arylmagnesium bromides. These *Grignard reagents* are very useful reaction intermediates because they are capable of reacting with a wide variety of organic functional groups under mild reaction conditions. Organic bromides can also react with

lithium to produce the more reactive but more expensive organolithium compounds, which are more convenient to use than Grignard reagents in some cases. Because of economic considerations these organometallic compounds are predominantly used in the synthesis of high-value products, such as pharmaceuticals or perfumes.

1.3. Production

Organic bromine compounds can be produced by a number of different chemical reactions [1–6]; however, addition and substitution reactions are the methods most commonly employed in industrial processes.

1.3.1. Addition Reactions

The uncatalyzed addition of bromine to olefins is rapid and quantitative, and can be used to analytically determine the amount of unsaturation in a molecule (bromine number). In the case of unsymmetrical reagents, such as hydrogen bromide (HBr), the addition to unsaturated compounds can proceed by ionic or free-radical reaction mechanisms. Under ionic reaction conditions and in the absence of peroxides, the product is the one that is formed from the most stable carbocation intermediate generated by the addition of a proton to the double bond (normal or Markovnikov addition). Because carbocation stability follows the order tertiary > secondary > primary, a 2-bromoalkane is the expected product when HBr is added to a 1-alkene:

$$RCH{=}CH_2 \xrightarrow{H^+} R\overset{+}{C}HCH_3 \xrightarrow{Br^-} RCHBrCH_3$$

Under free-radical reaction conditions the reverse order of addition to olefins occurs (abnormal or anti-Markovnikov addition). Thus the reaction of HBr with a 1-alkene in the presence of a peroxide or other free-radical initiator produces a 1-bromoalkane. The reaction proceeds by radical chain-initiating and chain-propagating steps, and the direction is based on the most stable free radical (tertiary > secondary > primary) generated by the addition of a bromine atom to the olefin:

$$RCH{=}CH_2 \xrightarrow{Br\cdot} R\dot{C}HCH_2Br \xrightarrow{HBr} RCH_2CH_2Br + Br\cdot$$

The free-radical addition of HBr is unique because the other hydrogen halides undergo addition to olefins only by the ionic pathway.

1.3.2. Substitution Reactions

Bromine and other reagents containing bromine can react with various organic compounds by substitution reactions that involve the replacement of hydrogen by bromine. In the case of saturated hydrocarbon substrates, such as alkanes and alkyl aromatic compounds, the bromination reaction occurs by a free-radical chain reaction and requires thermal, photolytic, or other forms of initiation:

$$Br_2 \longrightarrow 2\,Br\cdot \text{ (initiation)}$$
$$RH + Br\cdot \longrightarrow R\cdot + HBr \text{ (propagation)}$$
$$R\cdot + Br_2 \longrightarrow RBr + Br\cdot \text{ (propagation)}$$
$$R\cdot + Br\cdot \longrightarrow RBr \text{ (termination)}$$

where R is alkyl or alkylaryl.

The reaction with most linear aliphatic hydrocarbons is not generally useful because hydrogen abstraction by bromine atoms occurs at random in the hydrocarbon, and the radical chains are short and not self-sustaining. Reaction selectivity is low because the carbon–hydrogen bond dissociation energy differences between the many secondary hydrogens in a long-chain alkane are negligible. Reaction selectivities are much greater with branched alkanes because of the greater energy differences between the different carbon–hydrogen bonds, such that tertiary alkyl bromides can be the predominant substitution product.

In the case of alkyl aromatic compounds, such as ethylbenzene, the substitution reaction is very selective because of the much greater energy differences between the radicals generated in the hydrogen abstraction step. Because the benzylic radical ($C_6H_5\dot{C}CH_3$) is much more stable than the primary radical ($C_6H_5CH_2CH_2\cdot$), 1-bromo-1-phenylethane is essentially the only product formed.

Aromatic compounds (ArH) undergo nuclear substitution reactions with bromine by a ratelimiting electrophilic addition to form an arenium ion intermediate followed by the rapid loss of a proton:

Replacement of hydrogen by bromine usually requires a Lewis acid catalyst when the aromatic compound contains deactivating (nitro) or weakly activating (alkyl) substituents. No catalyst is required for the bromination of more activated aromatics, such as phenol or aniline. The amount and orientation of bromine substitution is dependent on a number of factors, such as stoichiometry, catalyst activity, reaction conditions, and substituent effects.

An equimolar mixture of bromine and chlorine (bromine chloride) can also be used for these substitution reactions. In free-radical substitutions the overall reaction is faster than with bromine because the more energetic chlorine atoms lower the energy of activation in the hydrogen abstraction step. Although minor amounts of chlorinated products are usually produced, bromine utilization is improved because HCl rather than HBr is produced as the byproduct. This reagent is often used in place of bromine for both aliphatic and aromatic substitution reactions when there are not adequate facilities to recycle or use HBr.

Other substitution reactions that are often used in commercial chemical processes include: the replacement of allylic and benzylic hydrogen atoms by bromine using *N*-bromo compounds, such as *N*-bromosuccinimide and 1,3-dibromo-5,5-dimethylhydantoin; the substitution of hydroxyl groups of alcohols by bromine using phosphorus compounds, such as phosphorus tribromide or triphenylphosphonium dibromide; and the replacement of chlorine atoms of many chlorinated hydrocarbons by bromine with various Lewis acids and phase-transfer catalysts. Various reagents can also be used to substitute the hydrogen atoms adjacent to carbonyl groups to produce the α-bromo derivatives of aldehydes, ketones, carboxylic acids, and active methylene compounds.

1.4. Commercial Products

Of the numerous organic bromine compounds that are commercially produced, the individual compounds discussed in this chapter were selected because of their industrial importance and because they illustrate the most common patented production processes. The order of treatment is by chemical reaction classification and begins with addition reactions, followed by substitution reactions of bromine for hydrogen, hydroxyl, and halogen. Because brominated flame retardants consume a significant amount of bromine, the production of this growing and important class of compounds is treated separately.

Most of these commercial products have different product quality specifications because they are generally produced by several manufacturers. Additional physical and chemical properties, first aid and personal protection information, toxicity and safety data, and proper precautions for handling, storage, and transportation are available from the manufacturers.

1.4.1. 1,2-Dibromoethane

Production. 1,2-Dibromoethane [*106-93-4*], $BrCH_2CH_2Br$ (ethylene dibromide), is manufactured by the uncatalyzed addition of bromine to ethylene.

The commercial process is carried out in a glass-column reactor consisting of a lower packed section and an unpacked upper section containing a number of superimposed, high-capacity, coil heat exchangers. Liquid bromine is continuously added above the packed section while a slight excess of ethylene is continuously fed countercurrently from the bottom of the packed section. The exothermic reaction between ethylene and bromine occurs in the liquid phase on the surfaces of the cooling coils, and heat is removed at a rate sufficient to maintain a maximum temperature of 100 °C in this section of the column. Some reaction also occurs in the gas phase above the bromine feed where product is condensed and separated from the vent gas (ethylene, HBr, and inert material). As the crude liquid product passes downward through the packed section, it provides a contacting surface for rising ethylene to convert any residual dissolved bromine. Ethylene dibromide is continuously withdrawn from the reactor into a hold-up tank where it is irradiated with ultraviolet light to eliminate minor amounts of unconverted starting materials. The technical-grade product is obtained in 99.5 % purity as

a clear, colorless liquid in close to quantitative yield [11].

A continuous process that claims lower corrosivity and high output of ethylene dibromide involves the countercurrent addition of bromine and ethylene plus the continuous addition of a cold concentrated aqueous solution of inorganic bromide, which functions as the heat exchange medium [12]. A process that uses ethylene dibromide as the reaction medium is also reported to allow good control of the exothermic reaction between bromine and ethylene [13].

Uses. The largest market for ethylene dibromide is in gasoline. It acts as a scavenger for lead alkyls and prevents buildup of lead oxides in automobile engines. This use, which amounted to about 35 – 40 % of United States bromine consumption in 1981, has been declining since 1974 as a result of the lead phasedown mandated by the U.S. Environmental Protection Agency (EPA). Government agencies in many other countries are following this course of action to decrease the amount of lead in the atmosphere. The continued production of nonlead tolerant automobiles and conservation policies will more than likely result in further declines.

The other major application for ethylene dibromide is for soil and space fumigation, and the postharvest fumigation of fruit. It was used as a substitute for DBCP (1,2-dibromo-3-chloropropane), $BrCH_2CHBrCH_2Cl$ [*96-12-8*], which was banned by the EPA in the late 1970s because workplace exposure led to azoospermia; it was applied to control pests, such as soil nematodes, rodents, and most species of insects. In late 1983 the EPA took emergency action to cancel the pesticide registrations for ethylene dibromide formulations used in most soil fumigation applications in the United States because of groundwater contamination. Some minor fumigation uses were allowed to continue, but the predominant volume of ethylene dibromide used in soil fumigation will cease.

Smaller amounts of ethylene dibromide are used as a reaction intermediate in the manufacture of other chemicals, such as the reactive flame retardant monomer, vinyl bromide [*593-60-2*]. Minor amounts are used as a high-density, nonflammable solvent in a variety of applications.

1.4.2. 1-Bromododecane

Production. 1-Bromododecane [*143-15-7*], n-$C_{12}H_{25}Br$ (lauryl or n-dodecyl bromide), is produced by the free-radical addition of gaseous HBr to 1-dodecene. Almost all industrial processes to manufacture the higher 1-bromoalkanes containing 6 – 18 carbon atoms employ this addition reaction. The alternative manufacturing process, the reaction of the corresponding alcohols with HBr, is not as economical because of the higher cost and lower reactivity of the alcohols compared to the olefins.

The continuous process is conducted in the liquid phase by contacting 1-dodecene containing a free-radical initiator with anhydrous HBr in a glass-lined reactor. Teflon (polytetrafluoroethylene) or Kynar (poly(vinylidene fluoride)) reactor linings are suitable alternatives. The reaction is usually carried out under moderate pressure to provide good mass transfer. Reaction temperatures of less than 20 °C are usually necessary to obtain high regioselectivity to 1-bromododecane.

Various continuous reactor designs that have been used to produce high ratios of primary to secondary alkyl bromides at higher temperatures (20 – 30 °C) include a two-stage reactor [14], and a thin turbulent rising film reactor [15]. The latter reactor operates by forming a thin film of olefin in a vertical tubular reactor, which is contacted with an upward stream of gaseous HBr to maintain turbulence and initimate mixing. Because residence times are short and the exothermic reaction is easily controlled by cooling the large surface area of the reactor tube, a 22 : 1 molar ratio of 1-bromo- to 2-bromododecane is obtained at 27 °C. When HBr is added to the olefin under batch reaction conditions, the rate of the competing ionic addition reaction increases and the molar ratio of primary to secondary bromides falls to 8 : 1 at comparable temperatures (32 °C).

The crude reaction product can be either flashed or contacted with an aqueous solution of sodium hydroxide to remove excess HBr. The conversion of 1-dodecene and the yield of 1- and 2-bromododecane are essentially quantitative.

Free-radical initiators that have been employed for this reaction are preformed olefin ozonides [16], olefin peroxides generated by preblowing air through the olefin [17], oxygen

[18] or phosgene [19] cofed with HBr, organic peroxides alone [20] or in the presence of phase-transfer catalysts [21], molecular sieves [22], and ultraviolet light [23].

Uses. *n*-Alkyl bromides have assumed considerable importance as starting materials for the production of many types of organic derivatives. The major use for *n*-alkyl bromides with 12 – 16 carbon atoms is in the production of alkyldimethylamines by the nucleophilic displacement of bromide ion with dimethylamine. These amines are used as intermediates in the manufacture of fatty amine oxides and alkyl dimethyl benzyl quaternary ammonium salts, which are used in a wide range of products because of their biological (germicidal) or physical (cationic) properties. Minor amounts of *n*-alkyl bromides are used to produce insect pheromones, phasetransfer catalysts, and other useful specialty chemicals.

1.4.3. 1-Bromo-3-chloropropane

Production. The versatile synthetic intermediate 1-bromo-3-chloropropane [*109-70-6*], $Br(CH_2)_3Cl$ (trimethylene chlorobromide), is virtually always produced by the free-radical addition of anhydrous HBr to allyl chloride.

Continuous or batch-type processes in glass-lined or impervious polymer-coated equipment can be employed. Gaseous HBr is added under slight positive pressure to a solution of allyl chloride dissolved in an inert, low-dielectric solvent using a free-radical initiator, such as oxygen [24], molecular sieves [25], organic peroxides [26], or ultraviolet irradiation [27].

Because of the inductive effect of the neighboring chloride group, the addition reaction is not as rapid or exothermic as the corresponding hydrobromination of 1-propene. The competing ionic addition to form 2-bromo-1-chloropropane [*3017-95-6*] is retarded to a much greater extent than the free-radical reaction so that low reaction temperatures are not necessary to achieve a high ratio of primary to secondary bromide. Metal ions that accumulate during allyl chloride storage in metal tanks or drums are usually removed because they can promote ionic addition.

The yield of crude product, which typically consists of 95 % primary and 5 % secondary bromochloropropanes, is about 95 % based on converted allyl chloride. The minor isomer can easily be separated by distillation if product specifications call for higher purity.

Uses. Trimethylene chlorobromide is a useful reaction intermediate to prepare γ-chloropropyl derivatives because of the greater reactivity of the bromine atom compared to the chlorine atom in nucleophilic displacement reactions. For example, the cyanide displacement of trimethylene chlorobromide forms γ-chlorobutyronitrile, an intermediate used for the production of herbicides, pesticides, pharmaceuticals, and other commercial products.

1.4.4. 1-Bromo-2-phenylethane

Production. The useful intermediate, 1-bromo-2-phenylethane [*103-63-9*], $C_6H_5CH_2CH_2Br$ (β-phenethyl bromide), is usually manufactured by the free-radical addition of HBr to styrene.

The typical batch process is run in a glass-lined reactor by sparging gaseous HBr through a solution of styrene in an inert solvent containing a free-radical initiator. The reaction, which is rapid and moderately exothermic, can be controlled by introducing HBr at about the rate it is consumed. When styrene is completely converted, any excess HBr that is present can be recovered by various techniques prior to recovery of solvent and product by distillation. Styrene conversions are usually quantitative and β-phenethyl bromide yields are typically 95 %. Although most patents describe batch reactions, the process can also be carried out continuously.

The essential features necessary to obtain high selectivities to the desired β-isomer and negligible amounts of the undesired α-isomer, 1-bromo-1-phenylethane [*585-71-7*], are the use of dilute solutions of styrene (< 30 wt %) in an inert, nonpolar solvent, such as heptane; reaction temperatures in the range of 40 – 95 °C; and the absence of water and free-radical inhibitors. Organic peroxides [28], oxygen or air [29], azo compounds [30], and irradiation by ultraviolet light or by ^{60}Co [31] are examples of free-radical initiators that have been employed for this reaction.

Although β-phenethyl bromide can be prepared in comparable yields by reaction of the more expensive β-phenethyl alcohol with phosphorus tribromide [32] or with other reagents, this alternative method is seldom used because of economic considerations.

Uses. β-Phenethyl bromide is an important starting material for the production of various β-phenethyl derivatives, pharmaceuticals, fragrances, and other fine chemicals.

1.4.5. 1-(Bromomethyl)-3-phenoxybenzene

Production. The synthetic pyrethroid starting material, 1-(bromomethyl)-3-phenoxybenzene [*51632-16-7*], 3-$C_6H_5OC_6H_4CH_2Br$ (*m*-phenoxybenzyl bromide), is produced by the thermal side chain bromination of *m*-phenoxytoluene. The usual byproduct from this benzylic bromination is 1-(dibromomethyl)-3-phenoxybenzene [*53874-67-2*], 3-$C_6H_5OC_6H_4CHBr_2$ (*m*-phenoxybenzal bromide).

The batch reaction is carried out in a glass reactor equipped with an appropriate HBr recovery system by feeding 20 % molar excess bromine vapor to neat *m*-phenoxytoluene at 265 °C. The rate of addition should be slow enough to avoid high local concentrations of bromine so that only negligible amounts of undesired ring-brominated byproducts are formed. Metal contamination must be avoided for the same reason and also to prevent Friedel-Crafts alkylation reactions. This uncatalyzed thermal bromination process produces the benzyl and benzal bromides in a 25 : 1 molar ratio in about 65 % yield based on 90 % converted *m*-phenoxytoluene. The low amount of *m*-phenoxybenzal bromide produced is partly due to its thermal instability, which results in the formation of some oligomeric byproducts at these high reaction temperatures [33].

Other thermal processes for brominating *m*-phenoxytoluene employ a catalyst, such as phosphorus trichloride [34], or activation with ultraviolet radiation [35]; however, appreciable amounts of ring-brominated byproducts are formed in these batch reactions. Continuous bromination of *m*-phenoxytoluene with ultraviolet light at 225 °C is claimed to eliminate formation of ring-brominated byproducts, but the product distribution of the benzyl and benzal bromides was not reported [35].

Additional *m*-phenoxytoluene brominating agents that have been used are $BrCCl_2CCl_2Br$ [36] and *N*-bromosuccinimide [37]. The former reagent is reported to produce mostly the benzyl bromide; the latter claims the predominant formation of the benzal bromide.

The competitive and analogous free-radical chlorination of *m*-phenoxytoluene to produce the corresponding benzyl chloride has been reported, but the reaction is not as selective as bromination and more ring-halogenated byproducts are formed.

Uses. Both *m*-phenoxybenzyl and *m*-phenoxybenzal bromides are important starting materials for the production of synthetic pyrethroid reaction intermediates. They can be converted by various reaction sequences to the alcohol, *m*-phenoxybenzyl alcohol, or to the aldehyde, *m*-phenoxybenzaldehyde, the key intermediates common to these synthetic pyrethroids. Both the alcohol and the aldehyde must contain less than 0.5 % ring-brominated byproduct for use in this application, hence the importance of minimizing the aromatic substitution side reaction.

1.4.6. Bromoacetic Acid

Production. Bromoacetic acid [*79-08-3*], $BrCH_2CO_2H$, and other α-bromocarboxylic acids are usually prepared by the well-known Hell-Volhard-Zelinski reaction in which the α-hydrogens of the carboxylic acid are replaced by bromine. A catalyst, such as a phosphorus trihalide, is necessary to convert the acid to the acid halide, the actual reaction intermediate. If the acid chloride or bromide is available as a starting material, no catalyst is needed and only one equivalent of bromine is required versus the two equivalents necessary when the carboxylic acid is the starting material. The resulting bromoacetyl halide can either be hydrolyzed or esterified to produce bromoacetic acid or its esters.

High yields of acid bromides can be obtained by adding one equivalent of bromine to the carboxylic acid containing phosphorus tribromide at 25 °C [38]. In practice a portion of the acid is converted to the acid bromide at 25 – 30 °C and then the remainder of the two equivalents of

bromine is fed over time at higher temperatures to complete the reaction. The intermediate, bromoacetyl bromide [*598-21-0*], is hydrolyzed by the controlled addition of water and the resulting bromoacetic acid is separated from the major impurity, dibromoacetic acid [*631-64-1*], by distillation. The hydrogen bromide byproduct that is evolved during the reaction and the hydrolysis is usually recovered as a concentrated aqueous solution for subsequent use in other processes or for recycle to bromine. Bromine utilizations can be improved by using bromine chloride as the brominating agent to produce bromoacetyl chloride [*22118-09-8*], which is subsequently hydrolyzed to bromoacetic acid and HCl [39].

If the corresponding α-chlorocarboxylic acid is available, it can be converted to the α-bromo-carboxylic acid by reaction with gaseous HBr catalyzed by aluminum chloride [40] or with concentrated hydrobromic acid and an azeotropic solvent to remove water and hydrochloric acid [41]. The nucleophilic displacement reaction of α-chlorocarboxylic acids with inorganic bromides, such as KBr or NaBr, is an alternative method [42]. The reaction of chloroacetic esters with hydrobromic acid to produce bromoacetic acid and an alkyl bromide from the ester portion of the molecule is another variation of the reaction [43].

Uses. Bromoacetic acid as well as other α-bromocarboxylic acids and their esters are used in many chemical processes as starting materials or as reaction intermediates.

1.4.7. Bromomethane

Production. Bromomethane [*74-83-9*], CH_3Br (methyl bromide), is produced from methanol and hydrogen bromide, which is generated in situ from bromine and a reducing agent like sulfur or hydrogen sulfide.

The commercial process is conducted by continuously feeding streams of liquid bromine, elemental sulfur, and methanol to a reactor maintained at 75 – 85 °C under a slight positive pressure. Methyl bromide vapor (99 % purity) is continuously withdrawn from the reactor overhead system and scrubbed free of dimethyl ether by contacting the gas with a sulfuric acid scrubber. Excess methanol and sulfur are used because some methanol is entrained in coproduced sulfuric acid and because some sulfur is consumed in formation of a thio acid byproduct. Sulfuric acid containing thio acid, sulfur, and methanol is continuously purged from the reactor and either processed for resale or treated for waste disposal. By operating at a higher temperature and pressure than described in other similar processes, this process allows for good control of the exothermic reaction, retards the formation of dimethyl ether, and produces methyl bromide in high yield and purity [44]. Some methyl bromide is produced by the decomposition of a brominated ester of the thio acid, thus the stoichiometry deviates somewhat from that shown in Equation 1; therefore, this process produces a 6 : 1 molar ratio of methyl bromide to sulfur, another process using hydrogen sulfide as the reducing agent [45] has the advantage of producing an 8 : 1 ratio (Eq. 2):

$$6\,CH_3OH + 3\,Br_2 + S \longrightarrow 6\,CH_3Br + H_2SO_4 + 2\,H_2O \quad (1)$$

$$8\,CH_3OH + 4\,Br_2 + H_2S \longrightarrow 8\,CH_3Br + H_2SO_4 + 4\,H_2O \quad (2)$$

Methyl bromide can also be coproduced with other useful organic bromine compounds by the reaction of methanol solvent with byproduct hydrogen bromide. Thus, when a solution of phenol in methanol is reacted with bromine, aromatic substitution produces a 96 % yield of the flame retardant intermediate, 2,4,6-tribromophenol [*118-79-6*], and hydroxyl substitution of the solvent produces methyl bromide in 34 % yield [46]. The flame retardant tetrabromo-bisphenol-A [*79-94-7*] and methyl bromide are obtained in 95 % and 61 % yields, respectively, by the similar bromination of bisphenol-A in methanol [47]. Even though methyl bromide yields are much less than theory because of the equilibrium, $CH_3OH + HBr \rightleftharpoons CH_3Br + H_2O$, favorable economics are achieved because less methanol and HBr need to be recovered, and a saleable coproduct is produced.

Uses. Methyl bromide is a colorless, odorless, nonflammable, poisonous gas at ambient temperature and pressure. It is primarily used as a space and soil fumigant to control a wide range of animal and plant pests and disease

organ-isms. In some of these fumigation applications methyl bromide containing the odorant, chloropicrin (Cl_3CNO_2), competes with ethylene dibromide.

A smaller but important use of methyl bromide is in the synthesis of many pharmaceuticals and fine chemicals, either as a methylating agent or as the Grignard reagent, methylmagnesium bromide [*75-16-1*].

1.4.8. 3-Bromo-1-propene

Production. The useful intermediate, 3-bromo-1-propene [*106-95-6*], $CH_2{=}CHCH_2Br$ (allyl bromide), is usually produced commercially from allyl alcohol and various brominating agents. The laboratory method of reacting allyl alcohol with hydrobromic acid and sulfuric acid is probably the most used process even though other reactants, such as red phosphorus and bromine [48], can be employed.

The batch reaction of allyl alcohol with a 35 % molar excess of 60 % hydrobromic acid is carried out in a stirred, glass-lined reactor at reflux (68 °C) for 3 h. The aqueous phase containing excess hydrobromic acid is separated and the organic phase is washed successively with water and aqueous sodium carbonate. Flash distillation produces allyl bromide (98 – 99 % purity) in about 75 % yield. An additional 6 % yield of allyl bromide can be recovered from the aqueous phases by extraction. The major impurity, 1,2-dibromopropane [*78-75-1*] formed by addition of HBr to the product, is readily separated by the distillation. Although the yield is lower than that from the similar process employing sulfuric acid (92 % yield), the process using 60 % hydrobromic acid has the advantage of higher reactor loading and does not require recycle of sulfuric acid [49]. Allyl bromide can also be prepared in 50 % yield by the halogen exchange reaction of allyl chloride with excess hydrobromic acid in the presence of a copper bromide catalyst [50]. The allylic bromination of propene by *N*-bromo derivatives or by bromine in the gas phase are alternative methods; however, they are not widely used commercially.

Uses. Allyl bromide is a very reactive intermediate capable of undergoing facile displacement reactions with many nucleophiles to produce synthetic perfumes, pharmaceuticals, and other compounds containing the allyl functionality.

1.4.9. Bromochloromethane and Dibromomethane

Production. Bromochloromethane [*74-97-5*], CH_2BrCl (methylene chlorobromide), can be produced from dichloromethane by a halogen exchange reaction using either liquid bromine or gaseous HBr:

$$6\,CH_2Cl_2 + 3\,Br_2 + 2\,Al \longrightarrow 6\,CH_2BrCl + 2\,AlCl_3$$

$$CH_2Cl_2 + HBr \xrightarrow{AlCl_3} CH_2BrCl + HCl$$

The unisolated bromochloromethane can be further brominated to produce dibromomethane [*74-95-3*], CH_2Br_2 (methylene bromide), by adjusting the reactant stoichiometry and some process variables:

$$6\,CH_2BrCl + 3\,Br_2 + 2\,Al \longrightarrow 6\,CH_2Br_2 + 2\,AlCl_3$$

$$CH_2BrCl + HBr \xrightarrow{AlCl_3} CH_2Br_2 + HCl$$

In the process using bromine to produce bromochloromethane, a stirred reactor is charged with aluminum filings and one-sixth of the total dichloromethane charge, followed by a small amount of bromine to initiate the reaction. When the reaction temperature approaches 35 °C the remaining dichloromethane, which is used in excess, is added, followed by the slower addition of bromine at a rate sufficient to maintain a mild reflux. After completion of the reaction, the crude reaction mixture is pumped to a hydrolyzer vessel from which the halogenated methanes are steam distilled. The crude product, which is separated from water, consists of 90 % bromochloromethane and 10 % dibromomethane in addition to unconverted starting material. Fractional distillation is employed to separate all three components. The overall yield is about 85 % based on the bromine that was used [51].

In the process employing HBr to produce dibromomethane, three reactors are connected for passage of a gas in series and each is charged with dichloromethane and aluminum chloride catalyst (5 mol %). Gaseous HBr is fed into the liquid phase of the first vessel and the evolved

gas from each vessel is fed into the next vessel in sequence. The gas exiting from the last vessel is principally hydrogen chloride. When the contents of the first vessel consist of 99 % CH_2Br_2 and 1 % CH_2BrCl, the composition in the second vessel is 46 % CH_2Br_2, 47 % CH_2BrCl, and 7 % CH_2Cl_2, and the composition in the third vessel is 18 % CH_2Br_2, 55 % CH_2BrCl, and 27 % CH_2Cl_2. This overall product composition corresponds to a 91 % utilization of the HBr fed. At this point the first reactor is discharged for recovery of product, recharged with starting materials, and reconnected to function as the last vessel in a new reaction sequence. The HBr feed line is switched from the first reactor to the second reactor, which becomes the first vessel in the next cycle. Thus, the third reactor in the original sequence operates as the second vessel in the new sequence [40].

Other patented processes to produce these materials include the gas-phase bromination of methyl chloride with a mixture of HBr and chlorine [52] or a mixture of bromine and chlorine [53], and the liquid-phase nucleophilic displacement reaction of dichloromethane with inorganic bromides in aprotic [54] and protic [55] solvents.

Uses. The major use for bromochloromethane is as a fire-extinguishing fluid in portable systems. Dibromomethane is primarily used as a solvent and as a gauge fluid. Both compounds have been employed as reaction intermediates for the production of several herbicides and pesticides.

1.4.10. Trifluorobromomethane and Difluorobromochloromethane

Production. Both trifluorobromomethane [*75-63-8*], CF_3Br, and difluorobromochloromethane [*353-59-3*], CF_2BrCl, are usually produced by substitution reactions involving the replacement of either hydrogen or chlorine atoms of fluorocarbons by bromine.

These reactions are carried out in the gas phase at elevated temperatures (450 – 650 °C) by continuously feeding the reactants through a tube reactor. To obtain high reaction selectivities to the desired halomethane, the most important process variables are contact times and the proper ratios of reactants, which in turn are dependent on the temperature and whether or not a catalyst is employed. In most cases starting material conversions range from about 40 to 90 % with product selectivities of 90 % or higher.

Trifluorobromomethane can be produced along with byproduct HBr by the gas-phase substitution reaction of trifluoromethane with bromine in a tube reactor packed with catalysts, such as alumina [56], or aluminum oxide – fluoride containing nickel [57]. Alternatively the reaction can be carried out by cofeeding trifluoromethane and bromine containing minor amounts of either sulfur trioxide [58] or chlorine [59] at elevated temperatures.

Other patented processes to produce CF_3Br include the disproportionation reaction of difluorodibromomethane (CF_2Br_2) catalyzed by aluminum chloride [60], and the zinc bromide – carbon catalyzed chloride exchange reaction of trifluorochloromethane (CF_3Cl) with hydrogen bromide [61].

Difluorobromochloromethane is produced by similar halogen exchange and disproportionation reactions. The gas-phase reaction of CF_2ClH with bromine in a tube lined with alumina (560 °C) produces a 96 % yield of a mixture of CF_2BrCl and CF_2Br_2 (15 : 1 molar ratio) based on a 91 % conversion of starting material [62]. The byproduct, CF_2Br_2, can be separated and converted to CF_2BrCl by the gas-phase reaction with chlorine [63].

Uses. Both halogenated hydrocarbons are employed as fire-extinguishing agents, especially in high-value applications, such as electronics and computer installations. They are just as effective as bromochloromethane but are much less toxic. Trifluorobromomethane is mainly used in automatic fire-extinguishing systems, and CF_2BrCl is primarily used in portable fire extinguishers.

1.4.11. Flame Retardants (→Flame Retardants)

Fires in industrialized countries inflict a heavy toll in terms of economic loss, human suffering, and death. In response to this problem, the chemical industry has developed and commercialized flame retardants to reduce the flammability and

to improve the fire safety of polymeric materials. Flame retardants are incorporated into polymers either by physical blending techniques, *additive type,* or by chemical methods in which part of a conventional monomer is replaced with a flame retardant monomer in the polymerization process, *reactive type.* Although reactive flame retardants have the potential for greater performance in the polymer (migration and leaching are traditional problems with polymer additives in general), economic considerations have limited their acceptance mostly to thermoset polymers, while the additive types are widely used in both thermoplastic and thermoset polymers.

In the late 1950s pentabromobiphenyl oxide was the first aromatic bromine flame retardant to gain commercial significance. Since then the development of new flame retardants has focused on products with increased molecular mass, such as decabromobiphenyl oxide and poly(tribromostyrene). The benefits of higher mass are lower volatilization during processing and reduced surface migration during polymer use. Other significant parameters that have been improved over the years with the introduction of new flame retardants are enhanced thermal, light, and chemical stability, reduced toxicity, and improved physical and engineering properties of the resulting polymer formulations. The major markets for flame retardants are the electrical, electronic, appliance, automotive, textile, and furniture industries.

A number of industrially important brominated flame retardants used in polymers are listed in Table 3. Although manufacturing procedures for these materials are not generally published, those described in this section are from the patent literature and illustrate the different types of processes that can be employed.

1.4.11.1. Tetrabromobisphenol-A

Production. Tetrabromobisphenol-A (TBBPA), 4,4′-(1-methylethylidene)bis-(2,6-di-bromophenol) [*79-94-7*], the largest selling brominated flame retardant, is produced by the bromination of bisphenol-A. The reaction is an example of substitution on an activated aromatic system and does not require catalysis.

The bromination reaction is generally conducted in solvents, such as a halocarbon [64], a halocarbon and water [65–67], a halocarbon and 50 % hydrobromic acid [68], or aqueous alkyl monoethers [69]. Aqueous acetic acid is also a satisfactory medium [70], and acetic acid with added sodium acetate is reported to improve product color [71].

The HBr byproduct can either be recovered and recycled to recover bromine values or utilized in situ by means of one of two techniques. The first method involves the addition of an oxidizing agent to the reaction medium to convert evolved HBr to bromine, which is subsequently consumed in the reaction. Suitable oxidizing agents are hydrogen peroxide [72], [73], sodium bromate [74], sodium chlorate [75], or chlorine [76], [77]. In the case of chlorine, the amount and rate of addition must be carefully controlled to limit chlorination.

The other approach is the use of an alcohol as the solvent to coproduce an economically useful alkyl bromide by the reaction of byproduct HBr with the alcohol [78]. Methanol is the solvent of choice because methyl bromide is widely marketed as a fumigant.

In the typical batch reaction, bromine in slight excess is added to a stirred bisphenol-A solution in methanol in a suitable reactor at 25 – 30 °C. The exothermic reaction is controlled by the rate of bromine addition, which is dependent on the refrigeration capacity of the reactor cooling system. After bromine addition, the contents of the reactor are heated to reflux (65 °C) for a short period to allow the slower reaction between methanol and dissolved HBr to occur. During this postreaction period, methyl bromide and some HBr are vented through the overhead condenser system into a series of scrubbers that neutralize and dry methyl bromide, which is produced in about 60 % yield based on byproduct HBr. Water is then added to precip-itate TBBPA and the resulting slurry is cooled, filtered, washed, and dried. The yield of TBBPA is generally 94 – 97 % based on bisphenol-A [47].

Uses. Commercial TBBPA is available in two grades, an epoxy resin grade and a higher quality polycarbonate grade. TBBPA is a reactive flame retardant; both hydroxyl groups can be reacted with epichlorohydrin under basic conditions to form the diglycidyl ether, which is widely used in epoxy resin formulations. TBBPA is also used in polycarbonate and ether

1.4.11.2. Decabromobiphenyl Oxide

Production. Decabromobiphenyl oxide (DBBPO), decabromodiphenyl ether, 1,1′-oxybis(2,3,4,5,6-pentabromobenzene) [*1163-19-5*], is manufactured by the exhaustive bromination of phenyl ether. As the bromination reaction progresses, partial substitution of hydrogen by bromine deactivates the aromatic ring toward further substitution, thus necessitating more vigorous reaction conditions than those used in the preparation of TBBPA. Lewis acid catalysis and an excess of bromine are used to obtain high conversions of the less reactive, under-brominated intermediates to DBBPO.

Decabromobiphenyl oxide can be prepared at atmospheric pressure by reacting bromine with phenyl ether in ethylene dibromide solvent and in the presence of aluminum bromide catalyst [79]. The use of bromine in an organic solvent requires long reaction times, results in low productivity per reactor volume, and necessitates recycling the solvent. These limitations have led to the use of bromine as both the reactant and the solvent [80–82].

A typical batch process to produce DBBPO [82] involves the addition of phenyl ether over one hour to an agitated reactor containing 150 % excess of the stoichiometric amount of bromine and catalytic amounts of aluminum bromide. The reaction temperature is maintained at 44–55 °C throughout the addition. After a 2-h postaddition reaction at reflux (59 °C), the product is recovered by first steam distilling the excess bromine from the reactor and then filtering the aqueous slurry. The resulting solid cake is washed with water and oven dried at 110 °C. The crude DBBPO, which consists of about 96 %

deca-, 3 % nona-, and 1 % octabromobiphenyl oxides, is obtained in high yield and contains small amounts of occluded bromine and hydrogen bromide. These occluded impurities can be substantially removed by first grinding and subsequently heating the crude DBBPO [83].

Uses. Decabromobiphenyl oxide is an additive-type flame retardant that has excellent thermal stability under conditions necessary to process high-impact polystyrene, the polymer system in which it is most widely used. It is also suitable for applications in ABS, rubbers, and some polyolefins and epoxy resins.

1.4.11.3. Tetrabromophthalic Anhydride

Production. Tetrabromophthalic anhydride (TBPA), 4,5,6,7-tetrabromo-1,3-isobenzofurandione [*632-79-1*], is prepared by phthalic anhydride bromination. Phthalic anhydride is a deactivated aromatic compound and is unreactive toward bromine under the usual bromination reaction conditions. TBPA can be prepared by reacting phthalic anhydride and bromine in a mixture of concentrated sulfuric acid and 70 % hydrogen peroxide in the presence of catalytic amounts of iodine [84], or in chlorosulfonic acid containing a small amount of sulfur [85].

The most common reaction medium is fuming sulfuric acid containing 45 – 65 % sulfur trioxide (oleum) and catalytic amounts of iron powder and iodine. If a mixture of bromine and chlorine is employed as the brominating agent, an excess of bromine must be present to limit the incorporation of chlorine in the product [86]. Use of bromine as the halogenating agent requires an excess of sulfur trioxide because it oxidizes byproduct HBr to bromine during the course of the reaction.

The batch reaction is typically carried out by adding 90 % of the bromine (2.1 mol/mol of phthalic anhydride) to the anhydride in excess oleum containing the catalyst at 90 °C. The reaction is completed by heating the reaction mixture to 105 °C followed by the addition of the remaining bromine. Excess sulfur trioxide and bromine are then distilled from the reactor and crude product is recovered from the cooled distillation residue by filtration. The product is thoroughly washed with water to minimize residual sulfuric acid, dried, and obtained in 94 % yield based on phthalic anhydride [87].

Uses. Tetrabromophthalic anhydride is primarily employed as a reactive flame retardant in unsaturated polyester and epoxy resin formulations. It is also used as an intermediate in the manufacture of other flame retardants, such as diallyl tetrabromophthalate and tetrabromophthalate polyol esters.

1.4.11.4. Hexabromocyclododecane

Production. The aliphatic flame retardant, hexabromocyclododecane (HBCD), is produced by the addition reaction of bromine to *trans,trans,cis*-1,5,9-cyclododecatriene, the cyclic trimer of butadiene. The HBCD that is obtained from this reaction consists of a mixture of stereoisomers of 1,2,5,6,9,10-hexabromocyclododecane [*3194-55-6*] ranging from oils to an isomer with a 205 – 208 °C melting point. Commercially available HBCD contains a mixture of solid isomers and has a melting point range of 170 – 180 °C (185 – 195 °C).

Addition of bromine to the cyclic triene in nonpolar solvents results in substantial amounts of free-radical substitution reactions which lead to decreased yields and lower quality product. Use of polar solvents, such as ethanol, reduces the substitution reaction but can give rise to vicinal bromoethoxy byproducts. Mixed solvent systems, such as benzene – *tert*-butyl alcohol [88] or perchloroethylene – ethanol [89], can be employed to improve product purities and yields.

Another technique to reduce the formation of undesired byproducts is to add the bromine and cyclododecatriene simultaneously and separately to ethanol [90]. This process is carried out by separately feeding bromine and cyclododecatriene in a molar ratio of 3 : 1 to 96 % ethanol in a stirred reactor. The reaction temperature is kept at 20 – 30 °C and a 1 – 5 % excess of bromine is maintained during the 2.5 – 3.0 h addition. The precipitated product is recovered by filtration or centrifugation, and the mother liquor is recovered and reused in subsequent reactions after adding makeup ethanol. The total yield of dried HBCD from nine separate batches using recycled mother liquor is 92 % [90].

Uses. The main use for HBCD is as an additive-type flame retardant for extruded and expanded polystyrene foam. Other applications include crystal and high-impact polystyrene, SAN resins, adhesives, and coatings.

1.5. Manufacturers

Organic bromine compounds that are produced in annual volumes of 100 t or more are generally manufactured by companies that also produce elemental bromine. Manufacturers with organic bromine production facilities near their bromine-producing plants have lower production costs than nonbromine producers because bromine shipping and handling costs are minimized and byproduct inorganic bromides can be readily processed to recover bromine values.

The major integrated producers are Dow Chemical, Ethyl Corp., Great Lakes Chemical Corp., and their various subsidiary companies in the United States; the Dead Sea Bromine Group, a member of Israel Chemicals Ltd. (Israel); Chemische Fabrik Kalk GmbH, a subsidiary of Kali and Salz AG (Federal Republic of Germany); ATOCHEM, a subsidiary of Elf Aquitaine (France); and Asahi Glass Company Ltd. and Toyo Soda Manufacturing Company Ltd. (Japan). Associated Octel Company Ltd. (United Kingdom), which manufactures large volumes of ethylene dibromide, can also be included in this group of producers.

1.6. Toxicology and Occupational Health

Organic bromine compounds having adopted TLVs and MAKs are given in Table 4.

1,2-Dibromoethane. Ethylene dibromide (EDB) is severely irritating to skin, eyes, and lungs; acutely toxic; and a profound CNS depressant [93–99]; sensitizer [93], [94], [97]; mutagen [100–105]; and carcinogen [95], [106–111].

Reproductive studies in mammals have demonstrated a no-effect or reversible effect

a) Data of 1983
b) Data of 2001

at nontoxic dose levels. Reduced egg weights of hens have been reported [112], [113]. Teratospermia in roosters could not be induced [113]; reproduction in rats could not be affected [114–116]. Ethylene dibromide has been reported to be nonteratogenic in rats [116]. Reversible spermicidal effects have been demonstrated in rats, rams, and bulls [117–122]. A dominant lethal effect in mice or rats, respectively, could not be demonstrated [123], [124].

Two metabolic pathways have been postulated. One involves a glutathione transferase mediated conjugation of EDB; the other is based on oxidative dehalogenation by microsomal enzymes yielding a free-radical intermediate [125].

Disulfiram (tetraethylthiuram disulfide) has been reported to potentiate EDB toxicity in mice and rats and carcinogenicity in rats [126–128]. Disulfiram, an inhibitor of aldehyde dehydrogenase, blocks detoxification of the EDB intermediate, 2-bromoacetaldehyde, which results in mutagenicity and DNA binding [129].

EDB has now been prohibited for use as a soil fumigant by EPA [130], and OSHA has proposed a reduction in permissible industrial exposure limits from 20 ppm to 0.1 ppm [131].

1-Bromododecane. No toxicology records exist in computer literature data bases (N.L.M., S.D.C., Dialog) from 1965 to 1984.

1-Bromo-3-chloropropane (TMCB). TMCB vapors cause severe eye and skin irritation, typical haloalkane cardiovascular effects [132], and CNS depression [133]. LC_{50} (fish): 75 mg/L/24 h [134]; BOD: 0.02 g/g, [135]; it is nonmutagenic (Ames); nondominant lethal; spermatogenesis was not impaired in mice treated at 300, 600, or 1200 mg/kg/d for 5 d [133].

1-Bromo-2-phenylethane. Phenylethylbromide has been reported to be metabolized by rats and rabbits to metabolites that are common to styrene and styrene oxide, and that are ultimately excreted in the urine [136], [137].

1-(Bromomethyl)-3-phenoxybenzene. 3-Phenoxybenzyl bromide is a skin sensitizer [133], [138]; LD_{50} (rats, oral): 5 g/kg male, and 2.3 g/kg female [133].

Bromoacetic Acid. Bromoacetic acid has an LD_{50} (oral, mice) of 100 mg/kg [139]; is irritating and corrosive to skin and mucous membranes [140], [141]. Biological in vivo or in vitro studies are based upon bromoacetate.

Bromoacetate administered as sodium bromoacetate to rabbits causes retinal degeneration, [142–144] and inhibits human erythrocyte carbonic anhydrase B [145].

Neuromuscular blockage by bromoacetate has been demonstrated [146]. Inhibition of neuroblastoma in A/J mice following intratumor injection has been reported. A mechanism involving irreversible binding of bromoacetate to cholinergic receptors on neuroblastoma cell membrane and/or to cholinesterase was proposed [147]. The antitumor action may be based on alkylation of DNA, not inhibition of cholinergic receptors [148].

The carcinogenic potential of chloroacetic acid has been studied in a 2-year (1982 – 1984) chronic gavage bioassay [149].

Bromomethane. Acute inhalation exposure causes pulmonary edema, convulsions, hyperthermia, and coma; chronic exposure can lead to neuropathies and behavioral disturbances. Significant changes occurred in rat brain monoamines following inhalation exposure to less than 15 ppm [150].

In addition to skin irritation and blistering, dermal exposure has been associated with systemic effects typical of inhalation exposure [151].

Methyl bromide has been reported to be mutagenic in a number of systems, but nonteratogenic [151]. It has been evaluated for carcinogenic potential by inhalation [149].

For further background, an excellent review article is recommended [151]. TLVs and MAKs are shown in Table 4. Ethyl Corp. has set an internal standard of 1 ppm, 8-h TWA [133].

3-Bromo-1-propene. Allyl bromide is extremely irritating and painful to the eyes, lungs, mucosal membranes, and skin [152].

Direct mutagenicity in the absence of activating enzymes has been demonstrated; the direct mutagenicity (allyl iodide > allyl bromide > allyl chloride) either decreased or was totally lost following addition of microsomal enzyme S-9 supernatant [153], [154]. Also in

vitro alkylation of DNA by allyl bromide was shown [155], [156].

Dibromomethane. The toxicity of dibromomethane has been summarized as follows [157]: more toxic than either methylene chloride or methylene chlorobromide, but less toxic than tribromomethane; can produce significant liver and kidney damage in animals; may cause cardiac arrhythmias; LD_{50} (rats, oral): >1 000 mg/kg; slightly irritating to the eyes and skin of rabbits and does not appear to be absorbed significantly even when applied repeatedly; vapors are anesthetic; disorder occurs in the protein-prothrombin and glycogenesis functions of the liver and in filtration capacity of the kidneys in animals; metabolized to carbon monoxide. Mutagenicity (Ames) has been demonstrated [158]; it has been reported as the most mutagenic among dihalomethanes [159].

Rats were observed to have elevated blood levels of carboxyhemoglobin following [^{13}C]-dichloromethane administration. It was later demonstrated in vitro that dihalomethanes were metabolized to carbon monoxide by a microsomal mixed function oxidase system [160], [161]. The reported rate and amount of carbon monoxide produced in vivo was as follows: dibromide > dichloride > chloride – bromide > diiodide [162]. The rate of metabolism by isolated rat hepatocytes was as follows: diiodide > dibromide > chloride – bromine = dichloride [163]. Further studies have shown that trihalomethanes are also metabolized to carbon monoxide [164]. The P450 pathway yields a reactive formyl halide intermediate which may either acylate tissue nucleophiles or decompose to carbon monoxide, hydrogen ion, and inorganic halide [164–167].

Dihalomethanes are also metabolized to formaldehyde, formic acid, and inorganic halide. Dihalomethanes were metabolized by rat liver homogenates to formaldehyde and organic halide [168]. An enzymatic pathway yielding a highly reactive intermediate capable of either alkylating tissue nucleophiles or undergoing metabolism to inorganic halide, formaldehyde, and formic acid was proposed [164], [166], [169]. Elevated urinary formic acid levels have been reported in workers exposed to high levels of dichloromethane [166]. The mutagenic activity of dibromo- and diiodomethane, involving an electrophilic intermediate, is mediated by microsomal enzymes and glutathione-S transferase [170].

Bromochloromethane. The most significant toxicological effects of bromochloromethane, as well as haloalkanes in general, are central nervous system depression [171] and impaired cardiac performance [172], [173], arrhythmias due to sensitization to epinephrine [174], [175], and decreased arterial blood pressure [176]. Two distinct activation in vivo pathways have been observed: a high-affinity, saturable oxidation reaction involving microsomal enzymes, and a much lower affinity pathway involving glutathione-S transferase [177]. The rate and amount of carbon monoxide metabolized is less than that following exposure to dibromomethane, but greater than dichloromethane [160]. Studies have also demonstrated adverse effects upon the liver, kidney, and adrenal cortex [178–180]; it is irritating to the eyes and skin [181]; LD_{50} (rats, oral), 5000 mg/kg [182]. Inhalation toxicity was reported to be greater than either dichloromethane or carbon tetrachloride [183]. The TLVs and MAKs are given in Table 4.

Trifluorobromomethane. Trifluorobromomethane causes central nervous system and respiratory depression [184], [185]; cardiac arrhythmias due to sensitization to epinephrine [174], [175]; reversible hypotension due to ganglionic blockage [176]; and impaired cardiac performance [172], [173].

The compound has been observed to inhibit acetylcholinesterase activity [186], [187]. For TLVs and MAKs, see Table 4.

Difluorobromomethane causes central nervous system depression [171], [188], [189], cardiac sensitization to epinephrine induced arrythymias, hypotension, and reduced myocardial performance [172], [173], [188], [189], and liver damage [190], [191].

Tetrabromobisphenol-A (TBBPA). Tetrabromobisphenol-A has a low order of acute toxicity [LD_{50} (rat, oral) > 5 g/kg, LD_{50} (rabbit, dermal) > 2 g/kg]; it is nonirritating to the eyes and skin (Draize scores of 0/24 h – 7 d and 0/24 h – 72 h, respectively); nonsensitizer; non-

mutagenic (Ames test); and nonbromacnegenic [133].

The uncoupling of oxidative phosphorylation by TBBPA in isolated rat liver mitochondria has been demonstrated; oxygen uptake decrease was also observed with the same concentration of biphenyl or biphenyl ether [192]. Adverse effects upon mitochondrial energy transfer reactions by polychlorinated biphenyls have been observed [193]. Also, TBBPA induced liver microsomal enzyme systems [194]. Ethyl Corp. has adopted a TLV of 2 mg/m^3, 8-h TWA [133].

Octabromobiphenyl Oxide (OBBPO). Preliminary studies have indicated that OBBPO causes developmental toxicity when administered as a corn oil suspension via gavage to pregnant rats on days 5 through 16 of gestation.

Administration of 26 mg/kg per day of the mixture, ranging from 6 bromine atoms to 9 bromine atoms per molecule, resulted in significant effects on the conceptuses including reduced average fetal body weights, increased embryo and fetal death (resorption), fetal malformation, and delayed skeletal ossification. The embryo and fetal no-effect level was defined at 2.5 mg/kg per day.

Decabromobiphenyl Oxide (DBBPO). Decabromobiphenyl oxide has also been shown to have a low order of acute toxicity [LD_{50} (rat, oral) and (rabbit, dermal) > 5 g/kg] [195]; nonirritating to the eyes [195], [196], but may cause transient irritation to the conjunctival membrane [196]; nonsensitizer to humans [197]; nonbromacnegenic [196]; nonteratogenic to rats [195], [196], [198]; no adverse reproductive effects in rats [198]; neither mutagenic [195] nor cytotoxic [198]; readily photodegraded by ultraviolet light [196]; and nonbioconcentrating in fish [196].

The principal target organs which may be adversely affected by DBBPO include the thyroid, liver, and kidney. Thyroid hyperplasia has been observed in rats following a 30-d feeding study at 80 and 800 mg/kg per day [196], [199]; no evidence of thyroid alterations was observed following a 2-year rat feeding study at 0.01 – 1.0 mg/kg per day [200].

Bromine concentration in the liver and adipose tissue of rats increased during a one-year feeding study at 0.1 mg/kg per day [198]; liver and kidney lesions were observed following a 30-d feeding study at dose levels > 80 mg/kg per day [196], [199]; liver alterations were observed following a rat inhalation study at 0.05 mg/L of air [195].

Liver enlargement in animals has been reported to occur with all brominated diphenyl ethers that are capable of inducing xenobiotic metabolism [201]. Neither DBBPO nor DBB (decabromobiphenyl) showed any porphyrinogenic potential [197]. There is evidence that porphyrinogenic effects of halogenated aromatic hydrocarbons are mediated through reactive intermediates, and apparently DBBPO is very resistant to metabolic degradation [202].

DBBPO was neither toxic nor carcinogenic in rats fed 0.01 – 1.0 mg/kg per day for 2 years [200]. DBBPO carcinogenicity potential is presently under evaluation [149].

Tetrabromophthalic Anhydride (TBPA) has a low order of acute toxicity [LD_{50} (rat, oral) and LD_{50} (rabbit, dermal) > 10 g/kg]; may cause moderate eye irritation (Draize score of 12/4/24 h); it is nonirritating to the skin, but is a potential sensitizer [133].

Neither TBPA [133] nor its hydrolysis product, tetrabromophthalic acid [203], are mutagenic (Ames).

Hexabromocyclododecane (HBCD) has a low order of acute toxicity: LD_{50} (rat, oral) >10 g/kg, LD_{50} (rabbit, dermal) >8 g/kg; LC_{50} (rat, 1 h): > 200 mg/L; nonirritating to eyes or skin (Draize scores of 0); nonmutagenic (Ames) [131].

2. Inorganic Bromine Compounds

The most important commercial inorganic bromine compounds are hydrogen bromide, hydrobromic acid, and the alkali bromides and bromates. The newest technology in the area is the utilization of aqueous inorganic bromide solutions (clear brines) by the petroleum industry as completion and workover fluids. Thousands of tons of zinc, calcium, and sodium bromide are used by the industry to help increase production rates and to extend well production life cycles [204].

2.1. Hydrogen Bromide and Bromides

2.1.1. Hydrogen Bromide

Hydrogen bromide [*10035-10-6*], HBr, M_r 80.9, is a colorless, corrosive, pungent gas that fumes on exposure to moist air and is extremely irritating to the eyes, nose, and throat. Physical properties of the anhydrous gas include:

mp	−89.6 °C
bp at 101.3 kPa	−66.8 °C
$t_{crit.}$	89.8 °C
$p_{crit.}$	8.509 MPa (85.1 bar)
heat of fusion at *mp*	31.1 kJ/kg
heat of vaporization at *bp*	215 kJ/kg
specific gravity (air = 1.00)	2.71

Hydrogen bromide is soluble in water, ethyl alcohol, other polar organic solvents, and acetic acid.

The anhydrous gas is produced industrially by burning bromine in the presence of excess hydrogen at 500 °C [205] or by reacting it with hydrogen at 375 °C over platinized silica gel or platinized asbestos catalyst. Generation of hydrogen bromide as a byproduct during bromination of aromatic compounds is another major source of the industrial gas. In either case, entrained bromine can be removed by scrubbing with phosphorous acid or by activated carbon [206]. The gas is liquefied by compression for storage and shipment in cylinders. Methods for laboratory preparation include reaction of bromine with tetrahydronaphthalene or with sulfur and water.

Anhydrous hydrogen bromide is commonly available in 99.8 % purity in cylinders containing 4.5, 13.6, or 59.1 kg at 2.2 MPa (22 bar) at 21.1 °C. The "Non-Flammable Gas" label is required for shipment.

Hydrogen bromide is utilized in the production of inorganic bromides by reaction with the appropriate aqueous solution or slurry of metal hydroxides, oxides, or carbonates; in the production of organic bromides by reaction with alkyl alcohols or alkenes; and as a catalyst for oxidations, alkylations, and condensations in organic chemistry.

In contact with metals in the presence of moisture, hydrogen bromide can produce hydrogen, which may form explosive mixtures with air. The acute inhalation LC_{50} for rats is 9527 mg/m^3 (2858 ppm). The TLV is 10 mg/m^3 (3 ppm); the MAK value is 20 mg/m^3; 16.7 mg/m^3 (5 ppm) is irritating to humans.

Hydrobromic acid is the aqueous solution of hydrogen bromide. The aqueous acid is commercially available as colorless 48 and 62 % solutions; they turn yellow on storage as the result of bromine formation caused by air oxidation or exposure to light. The "Corrosive" label is required for transportation by truck or rail.

Constant-boiling hydrobromic acid distills at 124.3 °C at atmospheric pressure and contains 47.6 wt % hydrogen bromide. The boiling point and hydrogen bromide concentration can be partially controlled by varying the pressure during distillation. These solutions are produced industrially by dissolution of hydrogen bromide in water. The densities of aqueous hydrobromic acid are shown in Table 5 (see below). A convenient laboratory preparation consists of distillation from a mixture of sodium or potassium bromide in dilute sulfuric acid. Hydrobromic acid is used industrially in the production of inorganic bromides, alkyl bromides, salts of organic nitrogen compounds, and as an alkylation catalyst.

The highly ionized aqueous solution can cause severe burns to the eyes, skin, and mucous membranes. Immediate removal by inundation with large amounts of water and subsequent medical attention are the recommended responses to accidental exposure.

2.1.2. Bromides

Metal bromides are routinely produced by reaction of hydrogen bromide or hydrobromic acid with metals, their hydroxides, carbonates, or oxides. Nonmetal bromides are produced by direct

Table 5. Densities of aqueous hydrobromic acid

c_{HBr}, wt %	10	20	30	40	50	60	65

reaction with hydrogen bromide or bromine at elevated temperature.

The alkali-metal bromides, particularly those of sodium, potassium, and lithium, are important industrial chemicals. Manufacture of each of these compounds is by reaction of the hydroxide or carbonate with hydrogen bromide or with bromine and a reducing agent, such as ammonia, formic acid, or carbon [207–209]. Concentration, filtration, and drying produces crystalline materials, whereas spray-drying results in a powder. Calcium and zinc bromides are the major non-alkali-metal bromides used industrially, although several others are used selectively.

Sodium bromide [*7647-15-6*], NaBr, M_r 102.9, d_4^{26} 3.20, *mp* 747 °C, *bp* 1390 °C, is a bitter, salty-tasting hygroscopic white solid. For its solubility in water, see Table 6 (see below). Sodium bromide can be isolated as the anhydrous compound from aqueous solution above 50.7 °C. The solid product is available in 25-kg plastic-lined bags, and a 45 % solution is available from 55-gallon drums (208 L) up to tank car quantities.

Sodium bromide is utilized for the preparation of light-sensitive silver bromide for photographic applications. Another use is as a bromine – hypobromous acid precursor for treatment of swimming pools, hot tubs, and industrial water. The bioactive agent is released by reaction of the bromide with an appropriate oxidant, such as chlorine. Sodium bromide solutions are also utilized by the petroleum industry as workover and completion fluids. They are particularly useful in geological formations containing high levels of carbonate – bicarbonate, which would form insoluble solids upon exposure to calcium halide solutions. Pharmaceutical-grade sodium bromide is prescribed for its sedative properties.

Sodium bromide solutions and the solid sodium bromide are considered moderate eye irritants, but nonirritating to the skin. The acute oral LD_{50} in rats is greater than 5 000 mg/kg and the acute dermal LD_{50} in rabbits is greater than 2000 mg/kg.

Potassium bromide [*7758-02-3*], KBr, M_r 119.0, d_4^{25} 2.75, *mp* 730 °C, *bp* 1435 °C, is a white, slightly hygroscopic crystal or powder with a bitter salty taste. For solubility in water, see Table 6. Potassium bromide is utilized for the production of photographic-grade silver bromide. It also finds use in process engraving, lithography, and in medicine as a sedative. It is considered moderately toxic and no special handling techniques are required.

Lithium bromide [*7550-35-8*], LiBr, M_r 86.9, d_4^{25} 3.46, *mp* 550 °C, *bp* 1265 °C, is used extensively as a 55 % solution for water absorption in air conditioning applications, in the lithium – bromine battery, and in medicine as a sedative. For its water solubility, see Table 6.

Exposure to lithium bromide may result in mild eye and skin irritation, whereas ingestion of large doses may cause central nervous system depression.

Ammonium bromide [*12124-97-9*], NH_4Br, M_r 98.0, ϱ 2.43 g/cm^3, sublimes at 452 °C (*mp* 542 °C in a sealed capillary); for its solubility in water, see Table 6. Ammonium bromide is a hygroscopic white to yellow-white crystal or powder that is freely soluble in alcohol and acetone. It is made by the reaction of hydrobromic acid and ammonia or preferably by the direct reaction of ammonia with bromine in water:

$$8\,NH_3 + 3\,Br_2 \longrightarrow 6\,NH_4Br + N_2$$

For safety, this reaction is run with ammonia in slight excess. Concentration of solutions produces the crystalline product, whereas a powder results from spray-drying. A 45 % solution is also available commercially.

Table 6. Solubilities of NaBr, KBr, LiBr, and NH_4Br in water (in g/100 g H_2O) at different temperatures (in °C)

Compound	−20	−10	0	20	40	60	80	100	120
NaBr	71.8		79.5	90.5	106	118	118.3	121.2	125.3
KBr		48.8	54.0	65.6	76.1	85.9	95.3	105	115
LiBr			131	151.3			210.5	227.9	
NH_4Br			59.5	74.2	89.8	105	117	135	

Ammonium bromide is used by the photographic industry, in process engraving, in textile finishing, as a flame retardant for wood, and in medicine as a sedative. It is a mild eye and skin irritant with moderate human toxicity.

Calcium bromide [*7789-41-5*], $CaBr_2$, M_r 199.9, d_4^{25} 3.35, *mp* 730 °C (some decomposition), *bp* 810 °C, solubility 142 g/100 g water, is a white, hygroscopic, odorless, salty-tasting crystal or powder. The hexahydrate, $CaBr_2 \cdot 6\,H_2O$, M_r 295.9, d_4^{25} 2.295, *mp* 38 °C, *bp* 149 °C (decomp.), is also available commercially.

Common manufacturing techniques include reaction of calcium hydroxide, oxide, or carbonate with hydrobromic acid or bromine and a reducing agent (formic acid [208], formaldehyde [210]). Vacuum concentration, filtration, and drying results in a crystalline product, whereas spray-drying produces a powder.

The major use for calcium bromide is as a component of high-density clear drilling, completion, workover, and packing fluids [211], [212]. By reducing formation damage, the use of clear brines results in higher production rates and longer production life. Calcium bromide is used in oil fields as a 95 % minimum purity solid in 25-kg plastic-lined bags or as a 53 % aqueous solution of specific gravity 1.70 – 1.71 at 15.5 °C. Calcium bromide finds other applications in photography, in medicine, in sizing compounds, as a wood preservative, and in flame retardant blends.

The oral LD_{50} for male and female rats is 2447 mg/kg; the solid and solution are recognized as primary eye irritants.

Zinc bromide [*7699-45-8*], $ZnBr_2$, M_r 225.21, d_4^{25} 4.20, *mp* 394 °C, *bp* 650 °C, solubility 447 g/100 g water at 20 °C, is an extremely hygroscopic, granular powder with a metallic taste. Aqueous solutions are highly acidic (pH 1 – 4). Manufacture is by reaction of zinc oxide with hydrobromic acid or with bromine and a reducing agent [209], [210]. Reaction of bromine water with zinc metal is an acceptable alternative but less desirable procedure.

A major new use for zinc bromide is as a completion and workover fluid for oil field application [213]. The normal article of commerce to the petroleum industry is a 2 301-kg/m^3 (19.2-lb/gal) solution consisting of 55 % zinc bromide and 20 % calcium bromide. A potential major new use for 77 % zinc bromide solution is in the zinc – bromine storage battery, which is being considered for use in utility load leveling [214] and as a power source for electric vehicles [215]. Other uses include photography and rayon manufacture; an 80 % solution of highly pure zinc bromide is used in nuclear reactor viewing windows.

Zinc bromide is not a primary skin irritant but is a severe eye irritant. The oral LD_{50}, combined male and female rats, is 1047 mg/kg. No hazard label is required for truck and rail shipments of solid zinc bromide; however, the acidic zinc bromide solutions require the "Corrosive" label.

Aluminum bromide [*7727-15-3*], $AlBr_3$, M_r 266.71, ϱ 3.01 g/cm^3, *mp* 97.5 °C, *bp* 263 °C (99.6 kPa), reacts vigorously with water. Aluminum bromide is a white to yellow hygroscopic solid which must be stored under moisture-free conditions. Manufacture is by direct reaction of aluminum and bromine or aluminum hydroxide and hydrobromic acid. Aluminum bromide is a very reactive catalyst for Friedel-Crafts reactions, olefin polymerizations, hydrocarbon isomerization, and olefin alkylation of aromatic compounds. It is commonly used as a catalyst in combination with aluminum chloride.

Aluminum bromide is extremely corrosive to human tissues and should be handled accordingly.

Copper(I) bromide [*7787-70-4*], CuBr (Cu_2Br_2), M_r 143.45, ϱ 4.98 g/cm^3, *mp* 492 °C, *bp* 1345 °C, is slightly soluble in water. Copper(I) bromide is prepared by addition of sodium bromide and sulfur dioxide to a solution of copper(I) sulfate. It is used for the preparation of aromatic bromine compounds via the Sandmeyer reaction and has limited use as a catalyst in polymer chemistry.

Phosphorus tribromide [*7789-60-8*], M_r 270.70, d_4^{15} 2.85, *mp* −40 °C, *bp* 172.9 °C, is produced by the reaction of bromine with yellow phosphorus in PBr_3 at 130 °C [216]. Reaction of organic alcohols with phosphorus tribromide results in the production of alkyl bromides. The

tribromide also serves as a catalyst in certain organic reactions.

Phosphorus tribromide is corrosive to the skin via hydrolysis to hydrogen bromide. A "Corrosive" label is required for rail and air shipment.

Bromine trifluoride [*7787-71-5*], BrF_3, M_r 136.9, d_4^{25} 2.80, *mp* 8.8 °C, *bp* 135 °C, is a colorless liquid produced by mixing fluorine with bromine. It reacts vigorously with water, organic compounds, and metals. The high specific conductivity of $8 \times 10^{-3}\,\Omega^{-1}\,cm^{-1}$ is due to dissociation:

$$2\,BrF_3 \longrightarrow BrF_2^+ + BrF_4^-$$

Bromine trifluoride is a strong fluorinating agent, which can be used in organic synthesis and in formation of inorganic fluorides.

Bromine trifluoride is highly toxic, corrosive to all tissues, and reacts violently with water. Both "Oxidizer" and "Poison" labels are required for rail shipment.

Bromine pentafluoride [*7789-30-2*], BrF_5, M_r 174.9, d_4^{25} 2.47, *mp* −61 °C, *bp* 40.8 °C, is a fuming, colorless liquid produced by reacting bromine and fluorine in an iron or copper vessel at 200 °C. This material is used as a fluorinating agent and as the oxidizer component of some rocket propellants. Highly toxic and corrosive to the skin, bromine pentafluoride requires the "Oxidizer" label for rail shipment and the "Corrosive" label for air shipment. The TLV is 0.1 ppm (0.7 mg/m^3), with an STEL of 0.3 ppm (2 mg/m^3).

Bromine chloride [*13863-41-7*], BrCl, M_r 115.4, *fp* −66 °C, *bp* −5 °C, is an orange-yellow liquid prepared by mixing bromine and chlorine in equimolar quantities. The reaction is exothermic and provision should be made for heat removal during production. At room temperature about 60 % of the mixed halogen is present as bromine chloride. Bromine chloride is used in organic synthesis both for addition across olefinic bonds, producing the bromochloro compound, and for aromatic bromination, whereby the aromatic bromide and hydrogen chloride are produced. It also finds use in water treatment.

This toxic and irritating material is a strong oxidizing agent and requires the "Corrosive" label for shipment by rail.

2.2. Hypobromous Acid, Hypobromites

Hypobromous acid [*13517-11-8*], HBrO, is somewhat unstable, existing as a dilute solution at ambient temperatures. Aqueous solutions can be prepared by reacting yellow mercuric oxide with bromine water [217]:

$$HgO + 2\,Br_2 + H_2O \longrightarrow 2\,HOBr + HgBr_2$$

Hypobromous acid, generated in situ, is a strong bactericide and water disinfectant. Alkali-metal hypobromites are normally prepared by reacting bromine with alkali hydroxide in aqueous solution below 0 °C:

$$2\,NaOH + Br_2 \longrightarrow NaBrO + NaBr + H_2O$$

At higher temperature, hypobromite disproportionates to bromate and bromide:

$$3\,NaBrO \longrightarrow 2\,NaBr + NaBrO_3$$

Hypobromites are used by the textile industry as bleaching and desizing agents.

2.3. Bromous Acid, Bromites

Bromous acid [*7486-26-2*], HOBrO, can be produced in low concentration by the treatment of a silver nitrate solution with excess bromine or by bromine oxidation in a diaphragm cell. Sodium bromite [*7486-26-2*], $NaBrO_2$, has been isolated as 99.6 % pure $NaBrO_2 \cdot 3\,H_2O$. The compound is stable and can be stored for extended periods of time under normal conditions. It is made from a concentrated hypobromite solution at pH 11 – 12 and < 0 °C:

$$2\,NaBrO \longrightarrow NaBrO_2 + NaBr$$

The bromine reacts in solution with remaining hypobromite forming sodium bromide and sodium bromate until an equilibrium is established. Ammonia is added to decompose the remaining hypobromite,

$$3\,NaBrO + 2\,NH_3 \longrightarrow 3\,NaBr + 3\,H_2O + N_2$$

leaving a solution from which yellow sodium bromite trihydrate can be isolated by concentration and filtration. Barium, calcium, and lithium bromites can be prepared similarly [218]. Bromites are used industrially as desizing agents for textiles and in water treatment.

Table 7. Solubilities of $NaBrO_3$, $KBrO_3$, and $Ba(BrO_3)_2$ in water (in g/100 g H_2O) at different temperatures (in °C)

Compound	0	20	40	60	80	100
$NaBrO_3$	27.5	36.4	48.8	62.6	75.8	90.8
$KBrO_3$	3.1	6.9	13.1	22.0	33.9	49.7
$Ba(BrO_3)_2$	0.287	0.657	1.33	2.32	3.65	5.71

2.4. Bromic Acid, Bromates

Bromic acid [*7789-31-3*], $HBrO_3$, has been prepared by reaction of alkali bromates with dilute sulfuric acid and by electrolysis of bromine water.

The industrially important salts of bromic acid, sodium and potassium bromate, are commonly produced by electrolytic oxidation of the appropriate aqueous bromide in the presence of dichromate at 65 – 70 °C [219]. The cathode may be stainless steel or copper and the anode is commonly lead dioxide or iron.

Another production method consists of reacting the aqueous alkali hydroxides or carbonates with bromine at elevated temperature:

$$6\,NaOH + 3\,Br_2 \longrightarrow NaBrO_3 + 5\,NaBr + 3\,H_2O$$

The relatively high solubility of the bromides allows the bromates to be recovered from the reaction solutions by cooling and filtration.

Sodium bromate [*7789-38-0*], $NaBrO_3$, M_r 150.9, d_4^{17} 3.34, *mp* 381 °C (decomp., oxygen evolution), is a colorless crystal or powder; for its solubility in water, see Table 7. Commercially, the most important material is 99.5 % minimum assay available in 50- or 113.6-kg polyethylene-lined drums. This strong oxidizing agent ("Oxidizer" label required) can cause fires upon contacting organic materials and will release bromine upon acidification or in a fire situation. Considered a skin and eye irritant, this material exhibits an oral LD_{50} in rabbits of 250 mg/kg. Its primary use is in hair treatment formulations. It has also been used in mixtures with sodium bromide in mining applications.

Potassium bromate [*7758-01-2*], $KBrO_3$, white crystals or powder, M_r 167.0, $d_4^{17.5}$ 3.27, decomposes at ~ 370 °C; for its solubility in water, see Table 7. Available as pure (≧ 99.5 %) and reagent (≧ 99.8 %) grade, its major uses are in flour treatment, in hair wave solutions, and as an analytic standard.

Barium bromate [*10326-26-8*], $Ba(BrO_3)_2 \cdot H_2O$, M_r411.2, exists as white crystals, ϱ 4.0 g/cm^3, which lose their water of crystallization upon heating to 180 – 200 °C, with decomposition occurring at ≈ 270 °C; solubility in water is given in Table 7. In addition to the reaction of bromine and barium hydroxide, barium bromate may be produced by reaction of a soluble barium salt with an alkali bromide. The insoluble barium bromate may be removed by filtration. It has limited use as a corrosion inhibitor.

1. Introduction

The name butadiene generally refers to 1,3-butadiene [*106-99-0*], C_4H_6, M_r 54.09. The thermodynamically less stable 1,2-butadiene [*590-19-2*], whichhas two cumulated double bonds, has only minor industrial importance. The1,3 isomer is economically the most important unsaturated C_4 hydrocarbon.

$CH_2=CH-CH=CH_2$ 1,3-Butadiene
$CH_2=C=CH-CH_3$ 1,2-Butadiene

CAVENTOU was the first to isolate butadiene, by the pyrolysis of amyl alcohol. BERTHELOT produced it by passing a mixture of acetylene and ethylene through a red-hot iron tube. In 1895 the structure of butadiene was elucidated by CIAMICIAN and MAGNAGHI. In 1886, ARMSTRONG and MILLER discovered butadiene in the products obtained on cracking petroleum.

Practical interest in butadiene and its derivatives began with the discovery by LEBEDEW in 1910 that butadiene forms rubberlike polymers. Butadiene was produced on a large scale in Germany prior to World War II and in the United States during the war. Simultaneously, methods were developed for the manufacture of useful butadiene polymers [1]. After the war, the work of ZIEGLER and NATTA, among others, on polymerization with organometallic catalysts led to higher quality rubber.

2. Physical Properties

Butadiene is a colorless gas under normal conditions. Some physical properties are summarized in the following [3], [4]:

bp at 101.3 kPa	− 4.4 °C
mp at 1013. kPa	− 108.9 °C
Critical temperature	425 K
Critical pressure	4.32 MPa
Critical molar volume	221 cm^3/mol
Density, liquid	
at 0 °C	0.646 g/cm^3
at 25 °C	0.616 g/cm^3
at 50 °C	0.582 g/cm^3
Gas density (air = 1)	1.87
Vapor pressure	
at − 4.4 °C	101.3 kPa
at 0 °C	120.0 kPa
at 25 °C	273.6 kPa
at 50 °C	537.9 kPa
at 75 °C	986.7 kPa
at 100 °C	1733 kPa
Viscosity, liquid	
at 0 °C	0.25 mPa · s
at 50 °C	0.20 mPa · s
Enthalpy of vaporization	
at 25 °C	20.86 kJ/mol
at − 4.4 °C	22.47 kJ/mol
Enthalpy of formation, gaseous, at 298 K, 101.3 kPa	110.0 kJ/mol
Free enthalpy of formation, gaseous, at 298 K, 101.3 kPa	151.5 kJ/mol
Enthalpy of combustion, gaseous, at 298 K, 101.3 kPa	2541.5 kJ/mol
Enthalpy of hydrogenation to butane, gaseous, at 298 K, 101.3 kPa	235.7 kJ/mol
Entropy of formation, liquid, at 298 K, 101.3 kPa	199.0 J mol^{-1} K^{-1}
Enthalpy of melting at 164.2 K, 101.3 kPa	7.988 kJ/mol

The technical data [2] important for reasons of safety are, above all, the flash point, − 85 °C, the ignition temperature, 415 °C, and the explosion limits when mixed with air and oxygen (Table 1). Unstabilized or insufficiently stabilized butadiene forms explosive peroxides with atmospheric oxygen.

Table 1. Explosion limits of butadiene in air (concentrations of butadiene stated) [5]

	At 101.3 kPa, 20 °C		At 490.4 kPa, 30 °C	
	vol %	g/m^3	vol %	g/m^3
Lower limit	1.4	31	1.4	150
Upper limit	16.3	365	ca. 22	ca. 2400

Table 2 lists azeotropic mixtures relevant to the distillation of butadiene-containing hydrocarbons.

Table 2. Binary azeotropic mixtures of 1,3-butadiene and of other C_4-hydrocarbons [6]

Mixture	*bp*, °C ∗	Composition
Butane/butadiene	min.	
trans-2-Butene/1-butyne		25.5 wt % 1-butyne
cis-2-Butene/vinylacetylene	min.	
Butadiene/2-butene	− 5.53	24.5 wt % 2-butene
Methylamine/vinylacetylene	− 6.8	2.5 wt % vinylacetylene
Ammonia/butadiene	− 37	45 wt % butadiene
Ammonia/1-butene	− 37.5	55 wt % 1-butene
Ammonia/isobutene	− 38.5	55 wt % isobutene
Ammonia/*n*-butane	− 37.1	55 wt % *n*-butane
Ammonia/isobutane	− 38.4	65 wt % isobutane
Methylamine/butadiene	− 9.5	58.6 wt % butadiene
Acetaldehyde/butadiene	5.0	94.8 wt % butadiene

∗ At 101.3 kPa.

Butadiene is sparingly soluble in water, see Table 3, soluble in methanol and ethanol, and very soluble in higher-boiling polar solvents, e.g., methylpyrrolidone.

Table 3. Solubility α of butadiene in water at 101.3 kPa (Bunsen's solubility coefficient) and solubility L of water in liquid butadiene

t, °C	α, m^3/m^3	L, g H_2O/kg butadiene
10	0.29	0.53
20	0.23	0.66
30	0.19	0.82
40	0.16	

3. Chemical Properties

Butadiene has two conjugated double bonds and therefore can take part in numerous reactions, which include 1,2- and 1,4-additions with itself (polymerization) and other reagents, linear dimerization and trimerization, and ring formation.

Polymerization. Polymerization by 1,2- and 1,4-addition is the most important reaction of butadiene [7].

cis-1,4-addition

trans-1,4-addition

isotactic 1,2-addition

syndiotactic 1,2-addition

The nature of these polymers depends greatly on the way in which they are prepared and on the catalyst system employed (→ Rubber, 3. Synthetic, Chap. 3.1.2.; → Rubber, 3. Synthetic, Chap. 3.2.1.).

Other Addition Reactions. Butadiene undergoes 1,2- or 1,4-addition with many reagents. The relative proportions of the 1,4- and 1,2-addition products depend on the reaction conditions such as temperature, solvent, reaction time. The addition products are important intermediates in the manufacture of, for example, chloroprene and hexamethylenediamine. A typical example of an electrophilic addition to butadiene is the reaction with hydrogen chloride.

Chloroprene [*126-99-8*] (**1**) is produced by the chlorination of butadiene followed by isomerizationof the 1,4-isomers and alkaline dehydrochlorination (→ Chlorinated Hydrocarbons, Chap. 6.4.3.1.):

1

In the production of *adiponitrile* [*111-69-3*] (**2**) and *hexamethylenediamine* [*124-09-4*] (**3**), [8], [9] hydrogen cyanide reactswith butadiene in two steps, and the adiponitrile thus obtained is hydrogenated to give the diamine. Typical catalysts are Ni^0 phosphine and phosphite complexes with Al/Zn promotors. Typical reaction conditions are 90 – 150 °C and ambient pressure in THF.

2 3

Several processes have been developed for the production of *1,4-butanediol* [*110-63-4*] from butadiene. In the three-stepMitsubishi process [10], [11], butadiene catalytically reacts with acetic acid to give 1,4-diacetoxy-2-butene (**4**), which in turn is hydrogenated to 1,4-diacetoxybutane and hydrolyzed to 1,4-butanediol. A similar process was reported by BASF [12].

4

The Toyo Soda process [13] for the preparation of 1,4-butanediol involves the reaction of the butadiene chlorine addition products 1,4-dichloro-2-butene and 1,2-dichloro-3-butene with sodium acetate or formate to give 1,4-diacetoxy-2-butene or 1,4-diformyl-2-butene, which are then hydrolyzed and hydrogenated to 1,4-butanediol.

The direct oxidation of butadiene with air or oxygen, a method introduced by Eastman Chemical [14], is an economic process for the production of several C_4 derivatives. In the oxidation 3,4-epoxy-1-butene (**5**) is formed with high selectivity. Thermal rearrangement of **5** followed by hydrogenation affords tetrahydrofuran, which can be hydrolytically ring opened to give 1,4-butanediol. Hydrogenation of **5** affords ethyloxirane (**6**).

5 6

The *Diels–Alder reaction* is one of the best known reactions of butadiene [15]. The dienophile is usually an olefin with an activated double bond, which reacts with butadiene to give a cyclohexene ring. This addition reaction, which is exclusively a 1,4-addition, can also take place with a second molecule of butadieneto give 4-vinylcyclohexene [*100-40-3*] (**7**) [16]. The reaction can take place withor without a catalyst [17–19]. Vinylcyclohexene can be dehydrogenated or oxidized to give styrene [*100-42-5*] [20].

7

Two molecules of butadiene can cyclodimerize to form 1,5-cyclooctadiene [*111-78-4*] and three molecules of butadiene

can cyclotrimerize to 1,5,9-cyclododecatriene [*4904-61-4*] [21]. Typical catalysts are Ni^0 complexes with phosphine or phosphite ligands. 1,5-Cyclooctadiene and 1,5,9-cyclododecatriene are important intermediates in the production of higher polyamides. 1,5-Cyclooctadiene can also be used to produce polyoctenamers via hydrogenation to cyclooctene and metathesis reaction.

Butadiene readily undergoes a reversible 1,4-addition with sulfur dioxide to form the cyclic sulfone 2,5-dihydrothiophene 1,1-dioxide [*1708-32-3*] (**8**) [22], [23], which is converted into sulfolan [*126-33-0*] (**9**), a heat-stable and highly polar solvent, by catalytichydrogenation.

Linear Dimerization and Trimerization; Telomerization. Butadiene forms linear dimers or trimers in the presence of Ni, Co, Pd, or Fe catalysts [24]. Since the linear oligomers of butadiene differ from each other by a chain length of four carbon atoms, their separation is easier than that of ethylene oligomers. Dimerization results in the formation of 1,3,7-octatriene [*1002-35-3*] and 1,3,6-octatriene [25], [26], which are, however, industrially uninteresting. The aromatic hydrocarbons xylene and ethylbenzene [27] can be made by the dehydrocyclization of 1,3,7-octatriene. If the dimerization is carried out under hydrogenation conditions, 1,7-octadiene and 1,6-octadiene are formed [28], [29]. 1,7-Octadiene is converted into a C_{10} diol by hydroformylation and into a C_{10} diamine by hydrocyanation and subsequent hydrogenation.

1,7-Octadiene

1,6-Octadiene

Dimerization of butadiene and simultaneous reaction with carbon monoxide and alcohol, followed by hydrogenation and saponification leads to pelargonic acid (*n*-nonanoic acid) [30], a starting material in the production of heat-resistant lubricants.

The telomerization of butadiene with a carboxylic acid [31] eventually results in 1-octene [*111-66-0*].

The telomerization of butadiene with water, a Kuraray process [32], and subsequent hydrogenation eventually results in *n*-octanol [*111-87-5*] with a selectivityof greater than 90 %.

The telomerization of butadiene with ammonia [*7664-41-7*] in biphasic liquid–liquid systems with palladium acetateand trisodium 3,3′,3″-phosphanetriylbenzenesulfonate as catalyst yields in high selectivity the primary octadienylamines 2,7-octadienylamine (**10**) and 3-

amino-1,7-octadiene (**11**) [33]. In biphasic systems the consecutive reactions to give the secondary and tertiary amines are dramatically suppressed in comparison to monophasic systems. The industrially important *n*-octylamine (starting material for softeners, corrosion inhibitors, flotation agents) is obtained by hydrogenation of 2,7-octadienylamine.

10 **11**

The telomerization of butadiene with carbon dioxide yields different products. Products, yields and selectivities depend on the catalyst type [34]. If $[Pd(acac)_2]/iPr_3P$ (acac = acetylactonoate) is used as the catalyst system, the δ-lactone **12** is formed in high yield and with high selectivity. This lactone could be of interest as a starting material for the synthesis of unsaturated and functionalized long-chain carboxylic acids.

12

Selective hydrogenation of butadiene to butene and complete hydrogenation to butane are possible. Industrially, these reactions are carried out with mixed C_4 fractions in cases of butadiene oversupply. The hydrogenated C_4 fractions are recycled to the steam cracker.

Formation of Complexes. Butadiene reacts with numerous metal compounds to form complexes, e.g., with Cu(I) salts, which were formerly used in the extraction of butadiene from C_4 hydrocarbon mixtures. This method has been replaced by modern extractive distillation techniques (Section 4.2). Complexes with other transition metalls like Fe, Ni, Co, Pd, and Pt are also well known.

4. Production

A series of articles was published in 1942 describing all the methods used to produce butadiene [35]. Historically butadiene was industrially produced from acetylene by two processes (Fig. 1)

Figure 1. Production of butadiene from acetylene

These methods are no longer used as the production of acetylene requires much energy and is expensive. Only the first steps of the Reppe process leading to 1,4-butanediol and tetrahydrofuran are commercially employed today. The production from ethanol [36], [37], was first developed by IPATJEW and OSTROMISLENSKY and was modified by LEBEDEW into a commercial process.

$$2\,CH_3CH_2OH \longrightarrow CH_2{=}CHCH{=}CH_2 + 2\,H_2O + H_2$$

This process, which operates at 370 – 390 °C on $MgO-SiO_2$ or $SiO_2-Al_2O_3$ catalysts with a selectivity of up to 70 % can be of interest for countries with cheap ethanol or a large surplus of agricultural alcohol. Nowadays butadiene is preferentially isolated from C_4 fractions obtained by cracking naphtha and gas oil to ethylene (→ Ethylene). The dehydrogenation of *n*-butane or *n*-butenes plays a minor role and is only operated on a campaign basis when there is a large enough differential between feedstock and butadiene prices.

4.1. Dehydrogenation of Butane and Butenes

The dehydrogenation reactions are endothermic, the following values being valid at 430 °C:

$$\text{Butane} \rightarrow \text{1-Butene} + H_2$$
$$\Delta H = 131\,\text{kJ/mol}$$
$$\text{Butane} \rightarrow \textit{cis}\text{-2-Butene} + H_2$$
$$\Delta H = 118\,\text{kJ/mol}$$
$$\textit{cis}\text{-2-Butene} \rightarrow \text{Butadiene} + H_2$$
$$\Delta H = 126\,\text{kJ/mol}$$

According to the Le Chatelier's principle, the yield is increased by decreasing the partial pressure of the reaction products. Practically, the dehydrogenation can be improved by conducting the reaction under vacuum or by addition of steam. The latter has the following advantages:

1) It reduces coking of the dehydrogenation catalyst
2) It provides the heat required for the endothermic dehydrogenation process
3) Steam can be easily separated from the reaction products by condensation

A further increase in yield is achieved by raising the reaction temperature.

Undesirable side reactions are cracking, isomerization, and polymerization. Compounds which tend to undergo these reactions are removed before the dehydrogenation process. As the dehydrogenation process does not proceed to completion, the reaction products must be separated, and the starting materials must be recovered and recycled into the dehydrogenation process.

Dehydrogenation of *n*-Butane. The best known one-step dehydrogenation is the Houdry Catadiene process (Fig. 2), which has been in operation on a commercial scale since 1943 [38–41]. In this adiabatic process, several packed-bed reactors, arranged parallel to each other, are operated alternatingly. Aluminum oxide mixed with approximately 20 % chromium oxide is the catalyst. *n*-Butane is subjected to dehydrogenation as such or in a mixture of *n*-butenes at 600 – 700 °C and 10 – 25 kPa. The use of high temperatures results in byproducts like $C_1 - C_3$ hydrocarbons, hydrogen, and carbon deposits on the catalyst. After 5 – 15 min of running time, the reactor is switched to regeneration. The heat generated by burning the coke residue during the regeneration phase is stored in the catalyst and in the added inert material and is then reused in the next reaction phase.

The concentration of butadiene at the outlet of the reactor is 15 – 18 %. During the recovery process, which includes absorption of the C_3 and C_4 hydrocarbons, compression, stripping, and separation from unconverted *n*-butane and *n*-butenes, the concentration of butadiene is increased to 30 – 50 %. Approximately 550 t of butadiene is obtained from 1000 t of *n*-butane.

Phillips Petroleum has developed a two-step dehydrogenation process [42], [43]:

1) *n*-Butane is catalytically dehydrogenated to butene at 600 °C and 1 bar on $Cr_2O_3 - Na_2O - Al_2O_3$.
2) The *n*-butenes are separated by extractive distillation with auxiliaries such as acetone, acetonitrile, and furfural.

3) The *n*-butenes are dehydrogenated to butadiene in an isothermic tubular reactor, heated with flue gas to 600 °C, at a pressure of 1 bar, with addition of superheated steam on a $Fe_2O_3 - K_2O - Al_2O_3$ catalyst.
4) Butadiene is recovered by extractive distillation with the above-mentioned auxiliaries and purified.

The advantages of this method are the longer running times without catalyst regeneration and higher butadiene yields (65 % based on butane).

Dehydrogenation of *n*-Butenes. *n*-Butenes are formed in the production of standard gasoline by catalytic cracking, in the production of olefins by thermal cracking, and in the dehydrogenation of LPG. Normally, butenes are a part of a C_4 hydrocarbon mixture. The C_4 paraffins can be separated from the C_4 olefins by extractive distillation, as routinely employed in the recovery of butadiene [42]. The boiling points of isobutene and *n*-butene are so close together that they can only be separated by special methods. The gas-phase BASF process employs 40 – 45 % H_2SO_4 to selectively convert isobutene into *tert*-butanol [48]. Today, separation is carried out by conversion to methyl *tert*-butyl ether or to isobutene oligomers [49–52]. Table 4 lists catalysts for the dehydrogenation of *n*-butenes to butadiene.

Oxidative Dehydrogenation of *n*-Butenes [53], [54]. The conversion and the selectivity of the dehydrogenation of *n*-butenes to butadiene can be significantly improved by removing the hydrogen from the equilibrium. The addition of oxygen causes the oxidation of hydrogen to water:

$$2\,C_4H_8 + O_2 \longrightarrow 2\,C_4H_6 + 2\,H_2O$$

The exothermic oxidation of hydrogen partially covers the heat requirements of the endothermic dehydrogenation reaction and, in addition, the oxygen, together with steam added during the reaction, leads to decreased catalyst coking. Especially productive methods are the Oxo-D process of Petro-Tex [55] and the O-X-D process of Phillips [56], [57].

The Oxo-D process was first applied on a large scale in 1965. The advantages of this method are the low consumption of steam and heating energy, high conversion and selectivity per reactor cycle, longer life span of the catalyst, and no necessity for catalyst regeneration. Petro-Tex achieved a 65 % conversion and a butadiene selectivity of 93 % by using a molar steam/butene ratio of 12/1.

Phillips has operated a plant in Borger (Texas) since 1970 based on the O-X-D process, producing 125 000 t/a of butadiene. Phillips also obtains a high conversion and a 88 – 92 % selectivity of butadiene.

The addition of oxygen to the dehydrogenation of butanes is not meaningful because at the high temperatures required, oxygen reacts with the reaction products to give undesired byproducts.

Oxidative Dehydrogenation of Butane with Iodine [58], [59]. Shell has developed a one-step dehydrogenation of butane to butadiene with iodine as the hydrogen acceptor. The addition of iodine enables a high conversion and yield of butadiene but causes serious corrosion problems in the plant.

4.2. Isolation of Butadiene from C_4 Steam Cracker Fractions

Today, the isolation of butadiene is based worldwide predominantly on butadiene-containing C_4 fractions from the steam cracking of ethane,

LPG, naphtha, gas oil, and other higher boiling hydrocarbon fractions to form ethylene and homologous compounds. In Western Europe, naphtha is primarily used as raw material. In the United States, however, liquefied petroleum gas (LPG) and natural gas liquids account for more than 70 % of the starting materials (→ Ethylene, Chap. 4.) [60].

Table 5 shows typical cracking yields and their relationship to the starting materials [61–63]. The influence of the cracking severity (temperature and duration) on the butadiene yield is minor compared to the influence exerted by the starting materials. However, the composition of the C_4 fraction itself is greatly dependent on cracking severity (Table 6).

Butadiene cannot be separated from this C_4 hydrocarbon mixture by simple distillation, because 1,3-butadiene and butane form an azeotrope (see Table 2). Hence, butadiene is isolated by liquid – liquid extraction or extractive distillation.

Table 7. Relative volatility of C_3- and C_4-hydrocarbons in comparison to butadiene (50 °C, infinite dilution) [70]

* NMP *N*-Methylpyrrolidone; DMF Dimethylformamide; DMAC Dimethylacetamide

CAA Liquid – Liquid Extraction [42]. The cuprous ammonium acetate (CAA) process, introduced by ESSO, is based on the ability of butadiene to form a complex with Cu^I compounds. Butadiene is separated from the C_4 hydrocarbon mixture by countercurrent extraction with Cu^I acetate in aqueous ammonia solution. This method is advantageous in the processing of C_4 fractions with a low butadiene and C_4 acetylene content, which is the case in dehydrogenation fractions [66]. A higher content of α-acetylenes (e.g., ca. 100 ppm of vinylacetylenes) strongly interferes with this process as a result of foam formation. Acetylenes, especially the unstable vinylacetylene, can be removed by selective hydrogenation before the isolation of butadiene [67–69].

Extractive Distillation. The method of choice for the isolation of butadiene from C_4 fractions is extractive distillation with selective organic solvents. The affinity of hydrocarbons to polar solvents depends directly upon their degree of unsaturation. A highly unsaturated hydrocarbon is not only more soluble in a polar solvent, but the solvent is also more effective in decreasing the volatility of the hydrocarbon (see Table 7).

The first plants using furfural as solvent were built in the United States during World War II (the process was developed by Phillips Petroleum) [42], [71]. The method introduced by Shell in the early 1950s uses acetonitrile as solvent. It was developed from a one-step procedure involving separate removal of acetylene into a two-step process [42]. Union Carbide has described a process based on dimethylacetamide [72]. Modern plants employ the BASF procedure [66], [73–76] with *N*-methylpyrrolidone or the DMF method [77], [78] of Nippon Zeon.

A flowsheet of the BASF process is shown in Figure 3 (see next page). *N*-Methylpyrrolidone (*bp* 203 °C at 101.3 kPa), containing 5 – 10 % water to increase the selectivity, is used as solvent. In the main washer (a), the more unsaturated hydrocarbons, such as acetylenes and diolefins, are dissolved in NMP, and the butenes/butanes are removed from the top of the washer. In a second extractive distillation step, in tower (c) and in the lower part of tower (b), the C_4 acetylenes and part of the 1,2-butadiene, which are more soluble in NMP than butadiene, are removed from the bottom of (c). The butadiene, which corresponds to specifications as far as alkanes, alkenes, and C_4 acetylenes are concerned, is removed from the top of tower (c) and is separated from the more volatile propyne in tower (h) and from the less volatile 1,2-butadiene and C_5 hydrocarbons in tower (i). The loaded solvent is led from the sump of tower (b) into tower (e) for complete degassing. Here the C_4 acetylenes are removed as a sidestream and, after selective hydrogenation, returned to tower (a). Recoveries of 99 – 100 %, based on the butadiene content of the C_4 feed, are achieved with selective hydrogenation of vinylacetylenes to butadiene [79]. An additional advantage of hydrogenation is the safe removal of the unstable C_4 acetylenes. Improper handling of C_4 acetylenes led to a severe explosion and complete destruction of a U.S. plant working with dimethylacetamide [80], [81]. Other efficient solvents for the extractive distillation of butadiene are given in [82]; e.g., methoxypropionitrile is used in some plants [85], [86].

Figure 3. BASF Extractive distillation process with NMP

In newer developments, C_4 acetylenes are removed by selective hydrogenation of the crude C_4 feedstock. UOP offers the KLP process, in which the crude C_4 stream is mixed with a stoichiometric amount of hydrogen and fed to a fixed-bed reactor containing a selective hydrogenation catalyst [83]. Temperatures are not allowed to exceed 85 °C. The reactor pressure is set to maintain the reaction mixture in the liquid phase. Because of catalyst fouling caused by polymeric materials that are produced during operation, catalyst regeneration by carbon combustion with air followed by catalyst reduction with hydrogen, is necessary every two months. The butadiene yield in comparison with a conventional two-stage extraction is increased from 95.5 to 99.5 %.

CDTECH offers the CDHYDRO process for acetylenes conversion in the crude C_4 feedstock [84]. The CDHYDRO process involves placing catalyst in the steam cracker debutaniser, adding hydrogen to the feed, and venting off any gases from the reflux receiver. Two modes of operation are available. In the first, the acetylenes concentration can be reduced to levels low enough to allow a single extraction system for butadiene purification, but with a loss of 3 – 4 % butadiene by hydrogenation. The second mode is only applicable with a double extraction unit. The acetylenes conversion is lower so that there is nearly no loss of butadiene. Unconverted acetylenes are extracted in the second stage and recycled to the debutanizer feed. Conversion of butadiene to butenes is less than 1 %.

5. Specifications of Butadiene

A typical butadiene specification to meet market requirements is listed in Table 8. The purity requirements have been intensified because the Ziegler-type catalysts employed in the stereospecific synthesis of rubbers are sensitive to,

Table 8. Typical specifications of butadiene

for example, allenes and acetylenes. The purity requirements are less stringent for butadiene used in emulsion polymerization, such as in the synthesis of styrene – butadiene rubber and latex [85].

6. Stabilization, Storage, and Transportation

Stabilization [78] involves protection against the action of oxygen and against polymerization. Butadiene forms dangerous polymeric peroxides [86], [87] with oxygen, which are viscous liquids sparingly soluble in liquid butadiene. They are deposited at the bottom of butadiene containers. Hence, the handling of butadiene requires complete exclusion of oxygen. In addition, inhibitors such as *p-tert*-butylcatechol (TBC) and 2,6-di-*tert*-butyl-*p*-cresol (TBK), are added because they are especially effective at scavenging radicals. They also prevent spontaneous polymerization of butadiene and can easily be removed by washing with aqueous sodium hydroxide. Aqueous sodium nitrite solution is also used as an antioxidant in the production of butadiene.

Butadiene can polymerize during production, storage, and transportion in three ways. Dimerization to vinylcyclohexene [88] is dependent on time and temperature and can be stopped by adding potassium cyanide solution to butadiene [89]. Second, butadiene can polymerize under the influence of oxygen and high temperatures, especially during manufacture, to give rubber-like polymers (fouling). Antioxidants such as TBC, exclusion of oxygen, low temperatures, and short exposures to higher temperatures reduce this polymerization [90]. Third, butadiene can polymerize, initiated by oxygen, high temperatures, and rust, to give a glassy, granular, opalescent, and very hard polymer (so-called popcorn) [90], [91]. It forms preferentially in off-stream tubes. Its growth is favored when popcorn seeds are present in the plant. The formation of popcorn in closed areas can lead to pressures of > 1000 bar, causing the bursting of off-stream tubes or containers. It can be prevented by the addition of TBC and by the careful elimination of all popcorn seeds. Popcorn is spontaneously inflammable in air and hence must be kept moist during its removal.

Liquified butadiene is stored at normal temperatures in liquid-gas containers or, preferably, for safety reasons at a temperature of 4 °C in almost pressureless containers. It is transported at normal temperatures and raised pressures in tankers, railroad tank wagons, and in ships. Especially in ships, temperatures of 4 °C and pressureless containers are required [92–94].

The following regulations must be followed when labeling and transporting butadiene:

- By road: Germany: GGVS, Class 2, no. 2F; Europe: ADR; USA: DOT regulations.
- By rail: Germany: GGVE, Class 2, no. 2F; Europe: RID; USA: DOT regulations.
- By inland shipping: GGVS/GGVE, Class 2, no. 2F; Europe: ADR.
- By sea freight: Germany: GGVSee: Class 2, no. 2F; International: IMDG Code.
- By air freight: International: IATA, Class 2, no. 2.1.

Butadiene is safely transported today in amonts greater than 100 000 t/a from, for example, Western Europe to Japan and to the United States.

7. Uses and Economic Importance

The majority of the butadiene produced worldwide is used as a monomer or co-monomer in the manufacture of synthetic rubber (→ Rubber, 3. Synthetic), above all for styrene – butadiene rubber and latex (SBR), polybutadiene rubber (BR), acrylonitrile – butadiene rubber and latex (NBR), and for chloroprene rubber (CR). Important plastics containing butadiene as a monomer component are impact-resistant polystyrene, a two-phase system consisting of polystyrene and polybutadiene; ABS polymers, consisting of acrylonitrile, butadiene, and styrene; and a copolymer of methyl methacrylate, butadiene, and styrene (MBS), which is used as a modifier for poly(vinyl chloride) (→ Polystyrene and Styrene Copolymers, Chap. 5.12.2.). In addition, butadiene is an intermediate in the synthesis of several important chemicals (Chap. 3).

The worldwide production capacity, production, and consumption of butadiene are summarized in Table 9 (see next page). Butadiene-containing C_4 steam cracker fractions are the

Table 9. Butadiene production, capacities, and consumption 1998 (in 10^3 t/a) [95]

	Production	Capacities	Consumption
USA/Canada	2020	2105	2218
Latin America	312	333	398
Western Europe	2000	2345	1752
Eastern Europe *	430	1080	452
Asia and Pacific	142	203	269
Middle East	160	267	33
Japan	1010	955	928

Africa			44
Total	7297**	8718***	7388

* Including the former Soviet Union. ** Production by extraction 7097×10^3 t/a, production by dehydrogenation 200×10^3 t/a.
*** Extraction capacity 8213×10^3 t/a, dehydrogenation capacity 505×10^3 t/a

starting material for more than 95 % of production. In Western Europe, naphtha is the principal raw material for steam cracking. High yields of butadiene are obtainied by this method, which explains the absence of dehydrogenation capacities. In the United States more than 90 % of the butadiene production is based on steam cracking. The available dehydrogenation plants are only used at times of butadiene shortage.

In the United States, Japan, and Western Europe, most of the butadiene rubber is required by the automobile industry. Table 10 shows the worldwide butadiene usage according to products [95]. In the 1950s and 1960s, new steam cracking plants were built worldwide, and the accumulation of butadiene as a byproduct of ethylene production resulted in a steady fall in the price of butadiene. The prices then dramatically rose after the oil crisis of 1973/74 and 1979/80. Figure 4 (see below) shows the effect on the butadiene prices in Western Europe. In 1986 a strong price drop, especially in Deutsche Mark, caused by a weak dollar, and a slightly weakened demand were noted.

Table 10. Butadiene usage in 1998 [95]

Application	Consumption	
	10^3 t/a	%
Styrene – butadiene rubber/latex	3440	46.5
Polybutadiene rubber	1986	27
Nitrile – butadiene rubber/latex	289	4
Polychloroprene rubber	189	2.5
Acrylonitrile – butadiene – styrene polymer	737	10
Adiponitrile	427	6
Others	320	4
Total	7388	100

In the early 1990s an oversupply of butadiene caused by increased cracking capacities led

Figure 4. Development of the price of butadiene in Western Europe, 1972 till first quarter of 1998

to a further price drop. This resulted, for example, in the hydrogenation of butadiene surplusses and use as cracker feedstock. Co-cracking of butadiene-containing C_4 streams was also used. Only with the increasing butadiene demand in the mid-1990s did a slight price relaxation take place. Up to 2010, an annual growth rate of 3 % worldwide is estimated for butadiene.

Only increasing butadiene prices could stimulate the manufacture of butadiene by the dehydrogenation and oxidative dehydrogenation methods. Dehydrogenation plants require ready access to energy and raw materials and high butadiene prices if they are to compete with the butadiene from steam crackers.

8. Toxicology

Workers usually are exposed to butadiene by inhalation. Contact of liquid butadiene with skin may exceptionally occur.

8.1. Experimental Toxicity Data

Acute Toxicity. Butadiene is of low acute toxicity. Lethal concentrations are: LC_{50} 12.5 vol % (rat, inhal., 2 h) and 11.5 – 12 vol % (mouse, inhal., 2 h) [96], [97]. Like some other hydrocarbons butadiene causes narcotic effects after inhalation of high concentrations, sometimes preceded by excitation and hyperventilation [98].

Repeated Short-Term Exposure. Rats, guinea pigs, rabbits, and one dog were exposed to butadiene at concentrations of 0, 600, 2300, and 6700 ppm for 7.5 h per day, 6 days a week during 8 months with no significant progressive injury occurring; only the highest concentration slightly retarded the growth and caused light cloudy swelling of liver in some cases. The data on fertility, hematology, body weights, blood biochemistry, urinalysis, and histopathology did not reveal any adverse effect to the animals [98].

In a similar study on Sprague-Dawley rats no clinical sign of toxicity was observed with the exception of moderately increased salivation, particularly at higher concentrations (4000, 8000 ppm). No adverse effects on growth rate, food consumption, neuromuscular function, hematological and biochemical parameters were recorded in the second, sixth, or thirteenth week of the test. Histopathologic investigations of the rats also did not demonstrate any change [99].

Mice were exposed to butadiene at levels of 0, 625 – 8000 ppm during 15 days or 14 weeks with no effect on survival or pathology during 15 days. Only the body weight decreased slightly at the 8000 ppm level. Exposure for 14 weeks resulted in dose dependent lower body weights and markedly increased mortality. No other effect has been reported [100].

Long-term Exposure. Groups of Sprague-Dawley CD rats were exposed to butadiene in air (0, 1000, 8000 ppm) on 6 h/day, 5 days/week for up to 105 (females) or 111 (males) weeks. The effects were: transient nasal secretion, slight ataxia, early increased mortality (at 8000 ppm concentration), suggestive higher frequency of spontaneous nephropathy in males (8000 ppm), higher liver weight, and a slightly increased incidence of metaplasia in the lung (males at 8000 ppm). Various tumors were identified with higher incidence in the exposed groups, others appeared earlier than in controls [101].

The authors concluded that butadiene was a "weak oncogen" under the conditions of this experiment. It is, however, questionable whether the small increase in mostly benign tumors and tumors with high background incidence like mammary tumors are biologically significant at these extremely high exposure levels.

Groups of $B6C3F_1$ mice were exposed to butadiene in air (0, 625, 1250 ppm) on 6 h/day, 5 days/week. Following week 60 for males and week 61 for females the study was terminated because of excessive mortality. Toxic and proliferative lesions of the nasal cavity occurred at increased incidence in the 1250-ppm group, but no neoplastic lesions were observed in the nasal cavity. Butadiene was also associated with liver necrosis as well as ovarial and testicular atrophy.

There was an early onset and a high incidence of several tumors including malign ones in the exposed mice. The authors concluded that there was clear evidence of carcinogenicity for butadiene. Mice obviously are much more sensitive to butadiene than rats are with respect to toxicity and carcinogenicity [100].

Mutagenicity. Gaseous butadiene was mutagenic in the Ames test only in the presence of liver microsomal enzyme preparations. This suggests the formation of a mutagenic intermediate (see Section 8.2) [102], [103].

Embryotoxicity and Teratogenicity. Groups of rats were exposed from day 6 through day 15 of gestation to various concentrations of butadiene [104]. There was an effect on body weight of the dams. The fetuses showed reduction of fetal weight at 8000 ppm (highest concentration) and an increased incidence of normally occurring variations, especially in wavy ribs, indicating retarded development, most prominent in the high-level animals. Major malformations occurred in two pups of one litter of the 8000-ppm group only. The 1000-ppm group did not exhibit higher incidences of malformed fetuses [104].

8.2. Metabolism

In vitro. 1,2-Epoxy-3-butene is formed when butadiene is incubated with liver microsomes and NADPH. Further metabolism involving epoxide hydratase yields 3-butene-1,2-diol [105–109]. The diepoxybutane and epoxybutanediol as well as conjugation products are postulated as further intermediates:

The formation of 1,2-epoxy-3-butene is significantly more pronounced in mouse liver tissue than in liver cells from rats, rhesus monkeys, and humans [109]. The experiments using lung tissues of the same species demonstrated the very rapid formation of 1,2-epoxy-3-butene in mice. However, rat lung preparations were capable of producing only one tenth of the amount seen in mouse lung preparations, whereas the epoxide could not be detected using monkey or human lung tissue. The formation of diepoxybutane could not be detected in any experiment [109].

In vivo. When rats were exposed to butadiene in a closed system, 1,2-epoxy-3-butene also was detected in the exhaled air [108], [109]. Mice in a similar experiment exhaled more of the monoepoxide than rats.

8.3. Human Data

Adverse effects after occupational exposure to butadiene are not reported in the literature. Volunteers exposed to a very high level of 8000 ppm of butadiene in air complained of eye irritation, blurring of vision, coughing, nasal congestion, and drowsiness. Subsequent repeated exposures did not suggest any cumulative effect [98], [110].

A hematology survey of workers at a styrene – butadiene rubber plant showed no pronounced evidence of hematological abnormalities in the peripheral blood. Exposure to butadiene was up to an average of 20 ppm in the tank farm area; in other departments less than 2 ppm occurred [111].

A retrospective study was conducted at two styrene – butadiene rubber plants involving 2756 male workers with an average duration of employment of approx. 10 years. No significant excess of total or cause-specific mortality has been found [111], [112]. Another mortality study covered a period of 36 years and reviewed a population of approx. 14 000 workers from styrene – butadiene rubber production facilities [114]. The study indicated that the overall mortality was lower as compared to general population (Healthy Worker Effect). There were no statistically significant differences in tumor mortality in total or for any specific cause of death.

Hygiene standards [115–117]. As a result mainly from the long-term mice study, butadiene is listed as an A 2 carcinogen with a TLV of 10 ppm by the ACGIH (1984/1985). The German MAK committee has withdrawn the MAK value, and butadiene is now listed in category

A 2 of the 1984 MAK list; a TRK value (lowest technically feasible level) will be established as a consequence.

The in vitro studies on the formation of critical intermediates in tissues from different species (mice, rat, monkey, man), however, suggest that the data from the long-term rat and especially from the mice study may not considered appropriate for direct use in risk evaluation for man.

1. Introduction

Butanals are saturated aliphatic C_4 aldehydes, C_4H_8O, M_r 72.11. There are two isomers: the straight-chain butyraldehyde [*123-72-8*] (butanal) and thebranched isobutyraldehyde [*78-84-2*] (2-methylpropanal, dimethylacetaldehyde).

Butyraldehyde

Isobutyraldehyde

Both aldehydes are found in minor concentrations in various essential oils, in plants, as well as in other natural substances [1], [2]. Both butyraldehyde and isobutyraldehyde are highly reactive intermediates that serve as versatile building blocks for many chemical syntheses, predominantly for the preparation of C_4-C_8 compounds.

The annual production volume of butyraldehydes is several million tones worldwide. The total production capacity for *n*-butanal is 6.8×10^6 t with a demand of 5.9×10^6 t. The annual growth rate is estimated to be 2–4 %. Production on an industrial scale is performed exclusively by hydroformylation (→ Oxo Synthesis) [3–5]. World-scale plants such as those operated by BASF, Oxeno (Degussa-Hüls), Celanese, and UCC have an annual output of $(200-600) \times 10^3$t.

2. Physical Properties

n-Butyraldehyde and isobutyraldehyde are colorless, flammable liquids with a pungent penetrating odor. Their vapors have a narcotic effect and irritate the mucous membranes. Both isomers are miscible with organic solvents, such as alcohols, ethers, and benzene. The solubilities of the butyraldehydes in water are collected in Table 1. Some physical data of the butyraldehydes are compiled in Table 2. Table 3 gives the composition of some binary and ternary azeotropes. Further physical properties are provided in [1], [2], and [6].

Isobutyraldehyde	water		60.5	6.0

3. Production

The only process used for manufacturing butyraldehydes is the hydroformylation (→ Oxo Synthesis) of propylene. The initially formed aldehyde can be hydrogenated to the corresponding alcohol, oxidized to the acid, or converted to other derivatives. Other routes, such as the hydrogenation of crotonaldehyde, prepared by the dimerization of acetaldehyde, and the dehydrogenation of butanols, are obsolete and not used on an industrial scale.

Hydroformylation of Propylene. In the hydroformylation process discovered by Otto Roelen at Ruhrchemie in 1938, a C_n olefin is treated with synthesis gas in the presence of a catalyst to form a C_{n+1} aldehyde. Transition-metal hydridocarbonyl complexes of the general formula $[HM(CO)_x]$ (M = Co, Rh, Ru) serve as a homogeneous catalysts. On an industrial scale, hydroformylation is carried out at 90 – 180 °C and 2.0 – 30 MPa [3–5].

Basically, all olefins, diolefins, or even functionally substituted olefins may be used as raw materials. On an industrial scale alkenes from C_2 to C_{18} are predominantly used. Propylene has gained particular significance, being converted to a mixture of *n*- and isobutyraldehyde. Although the reaction medium is homogeneous in most processes, a two-phase process (water/organic solvent) has also been developed, with advantageous catalyst separation and optimized energy consumption.

Depending on the oxo catalyst, the reaction conditions, and the process design, mixtures of butyraldehydes with a *n*/iso ratio from 1/1 to 20/1 are obtained. In addition to the aldehydes, which constitute 90 – 98 % of the reaction mixture, minor amounts of byproducts and secondary products of the reactive butyraldehydes are formed, such as butyl formate, butanols, and aldehyde dimers, trimers, and condensation products [3–5].

Oxo Technology [7]**.** The oxo reaction (hydroformylation) is the reaction of synthesis gas (CO/H_2, usually with a 1/1 molar ratio) with an alkene (see also → Oxo Synthesis). Terminal olefins yield a mixture of *n*-aldehydes and 2-methylaldehyde isomers, the so-called isoaldehydes. The reaction is catalyzed by rhodium or cobalt metal complexes. With unmodified hydrido rhodium or cobalt species the *n*/iso ratio is usually poor. By addition of ligands like triphenylphosphine (TPP) in homogeneous systems or trisulfonated triphenyl phosphine

(TPPTS) in water/organic two-phase systems the *n*/iso ratio is significantly enhanced. In particular at low temperatures, at high carbon monoxide partial pressure, and at a high ligand concentrations the formation of the straight-chain isomers is favored [3–5].

Early versions of the oxo process used cobalt catalysts at relatively high pressures (20 – 35 MPa), whereby $[HCo(CO)_4]$ is the active catalyst species. The typical *n*/iso ratio is about 4/1 with propylene as feedstock. By the mid-1900s various companies (e.g., BASF, ICI, Eastman) had developed their own versions of the cobalt process. For short-chain olefins like propylene, the cobalt technology has almost fully been substituted by rhodium-based processes. Only for higher and in particular branched olefins is cobalt still the most widely applied metal. The second-generation, phosphine-modified cobalt hydroformylation catalysts were developed in the 1960s by Shell.

In the 1970s UCC and Celanese developed a low-pressure oxo process (LPO) with Rh as metal and triphenylphosphine (TPP) as ligand. This process operates at a lower pressure and yields a n/iso ratio of about 10/1. Versions of this process with a gas recycle step are commonly known as LP Oxo Mk I (early version) or Mk II. A further proposal is the LPO Mk III process with improved raw material usage and a liquid catalyst recycle. The product/catalyst separation is performed in a separate vessel in which the aldehyde vapors are flashed off and the liquid solution containing the rhodium catalyst is recycled to the reactor. In this operating mode, the aldehyde condensation products serve as a solvent for the catalyst. However, the application of all versions is mostly limited to propylene and butene hydroformylation. Many plants have been converted from high-pressure cobalt to LPO technology for new or additional butyraldehyde (and thus butanol and 2-ethylhexanol) capacity.

By the mid-1980s Ruhrchemie (now Celanese) and Rhône-Poulenc developed a two-phase process with a water-soluble rhodium/TPPTS complex. The major advantages are the simple and mild catalyst recycle, the high *n*/iso ratio of ca. 20/1 and the beneficial low energy consumption of the whole process [3–5], [8].

The fourth generation of oxo catalysts used for the production of butyraldehyde and especially of higher aldehydes (and thus less important for synthesis of butyraldehyd) is known as the LPO Mk IV version. This process applies highly active bis-phosphite-modified rhodium catalysts which are suitable for both propylene and raffinate II feedstocks for butyraldehyde and valeraldehyde, respectively. The high catalyst activity allows this process to be run in single-pass mode with no olefin-recycle requirements. The potential of this process is its flexibility to convert propylene or butenes in the same reactor system.

Process Technology. For homogeneous reaction systems, the standard processing of the crude hydroformylation product, containing *n*- and isobutyraldehyde, rhodium metal, ligand, and byproducts, is generally the distillation of the reaction mixture to separate the aldehydes from the catalyst solution. To minimize catalyst decomposition, phosphine-modified cobalt or rhodium catalysts are separated from the reaction product by fast flash distillation. The less volatile catalysts remain at the bottom and are recycled to the hydroformylation reactor without further treatment. However, optimized catalyst lifetime and thus improved activity and selectivity requires the discharge of a small portion of the catalyst for workup and addition of fresh catalyst.

In contrast to the homogeneous hydroformylation processes, the Ruhrchemie/Rhône-Poulenc process (RCH/RP) is designed on a completely different reaction and catalyst recovery system. In principle the two-phase RCH/RP process applies a stirred tank reactor, followed by a phase separator and a stripping column. The reactor containing the aqueous catalyst solution (Rh/TPPTS) is fed with propylene and synthesis gas. The crude oxo product is passed on to the phase separator, where gaseous components are removed and the liquids separated into two phases, the aqueous catalyst solution and the organic aldehyde phase. The catalyst solution is recycled to the reactor via a heat exchanger system, which generates steam. This results in one of the advantages of the two-phase technology: the high energy efficiency. The P/Rh ratio is kept above 20/1 to ensure an *n*/iso ratio of at least 95/5. Almost no rhodium is leached out of the

water phase. The organic phase containing the crude aldehydes is stripped with synthesis gas to remove dissolved propylene, which is recycled to the reactor. The raw aldehyde mixture is split into iso- and *n*-butyraldehydes in a distillation unit.

Hydrogenation of Crotonaldehyde. Before the discovery of the hydroformylation reaction, the aldol condensation of acetaldehyde to give crotonaldehyde followed by hydrogenation to *n*-butyraldehyde was the most important method of producing *n*-butyraldehyde.

n-Butanol is formed as a byproduct by hydrogenation of the aldehyde moiety during the selective hydrogenation of the double bond of crotonaldehyde. Selective hydrogenation is performed in gas- or liquid-phase processes. Typical catalysts applied are supported catalysts on the basis of Cu, Ni, Pd, Ru, Fe, Cr, or Mn [1], [9–14].

Up to the 1950s this route was still the preferred method for producing *n*-butyraldehyde [15] on an industrial scale, but the convenient one-stage oxo processes replaced crotonaldehyde hydrogenation almost completely. Only countries with massive ethanol production based on natural resources, such as Brazil, might rediscover the crotonaldehyde route for producing *n*-butyraldehyde [15].

Dehydrogenation of Butanols. Butanols formed in other processes, such as Fischer – Tropsch synthesis [16], alcoholic fermentation of sugar with *Clostridium saccharobutylacetonium liquefaciens* or *Bacillus amylobacter* [17], and Reppe carbonylation [18], can be dehydrogenated to butyraldehydes.

$$CH_3CH_2CH_2CH_2OH \rightleftharpoons CH_3CH_2CH_2CHO + H_2$$

The reaction is carried out in the gas phase with a heterogeneous catalyst [19]. The addition of hydrogen acceptors such as O_2, either pure or as air, increases the aldehyde yield but also the formation of byproducts. Zinc- and/or chromium-doped copper catalysts are particularly effective [20], [21].

Fischer – Tropsch synthesis generates small amounts of *n*-butyraldhyde, which is of importance in some local markets [16], [22].

4. Stabilization, Testing, and Quality Specifications

Stabilization. The reactivity of butanals is determined by the polarity of the carbonyl group. The inductive effect of the carbonyl group promotes α-proton abstraction, which allows a broad variety of consecutive intermolecular reactions, with addition type reactions as the most important examples. Thus it is recommended to handle aldehydes during distillative work-up, storage and shipment only under the following precautions:

- Inert gas atmosphere for all reaction and work-up steps
- Storage with exclusion of UV light
- Storage at constant and moderate temperature
- Conversion into thermally stable compounds like acetals, which are easily cleaved back to the aldehydes
- Addition of stabilizers and antioxidants

Testing. The most important method of testing and continuous control of product quality (Table 4) is gas chromatography with a low injection temperature to avoid decomposition of impurities, e.g., aldols.

In the analysis of butyraldehydes it is important to detect trimeric aldehydes, which are formed readily, especially in the absence of stabilizers. Since these trimerization reactions are catalyzed by acids, contact with acidic compounds must be strictly avoided during the course of aldehyde processing. During the analysis of water in butyraldehyde by Karl Fischer titration, special precautions must be taken to avoid condensation to acetals, which is accompanied by formation of water. This is achieved by the use of a solvent mixture composed of four parts pyridine and one part ethylene glycol. The density and refractive index of the water-containing product are strongly affected by the

equilibrium hydrate concentration, which is established slowly. During determination of the acid number care must be taken to exclude atmospheric oxygen. The boiling point of the butyraldehydes is strongly affected by traces of water.

Quality Specifications. Table 4 outlines the standard quality specifications for butyraldehydes. The limits are largely determined by the intended use and by specific customer requests.

5. Handling, Storage, and Shipment

The butyraldehydes are stored and shipped in containers of corrosion-resistant steel, aluminum, glass, or ceramic, as well as specially coated tanks of normal steel and drums with removable polyethylene inserts. Even with water contents below 0.1 % and storage under inert gas, *n*-butyraldehyde dissolves iron from steel, causing discoloration of the product.

On contact with air butyraldehyde is oxidized readily to the butyric acids. Therefore, storage under inert gas is mandatory. Even traces of acids catalyze the trimerization of isobutyraldehyde. In general this may be prevented by the addition of a suitable amine (e.g., triethanolamine) or other bases [24].

Owing to the low flash points and ignition temperatures (Table 5) as well as the high volatility of these aldehydes the safety regulations are to be strictly observed.

The butyraldehydes are shipped in tank cars or trucks, tankers, or drums. The classification and designations for the various modes of transport must be observed (Table 5).

6. Chemical Reactions and Applications

Owing to their reactivity butyraldehydes are important starting materials for a broad variety of products [30]. Due to the high reactivity of the carbonyl group, aldehydes undergo many organic chemical reactions. Typical aldehyde reactions are:

- Addition to the C=O bond without substitution of the oxygen atom
- Addition to the C=O bond under substitution of the generated hydroxyl group
- Substitution of the oxygen functionality
- Formation of enol derivatives
- Oxidation
- Reduction
- C–C bond cleavage
- C–C bond formation.

Figure 1 outlines the reactions applied on industrial scale.

Butyraldehydes are important intermediate products for a vast number of C_4 products, including *n*-butanol, *n*-butyric acid, *n*-butylamines, and butyl acrylates, as well as for the plasticizer alcohol 2-ethylhexanol (C_8) and for C_6 products such as 2-ethylbutyric acid. Isobutyraldehyde is converted mainly to isobutanol and neopentyl glycol. Isobutyric acid is a potential intermediate for methacrylic acid (→ Methacrylic Acid and Derivatives, Chap. 3.3.).

Hydrogenation. The butyraldehydes are converted to the corresponding butanols by catalytic hydrogenation, whereby both liquid-phase and gas-phase processes are used. The

mild, highly selective gas-phase hydrogenation is carried out on nickel or copper supported catalysts.

Oxidation. Pure oxygen or air converts butyraldehydes to carboxylic acids in high yields, the reaction taking place in the presence or even absence of a catalyst. Transition metals of Groups 5 – 10, Cu, Ag, Ce, the alkali metals, and alkaline earth metals are suitable catalysts. If oxidation is carried out in the liquid phase, the metal naphthenates or carboxylates are used. In gas-phase processes, generally metal oxides, deposited on carriers such as silica gel, kieselguhr, silicates, quartz, or alumina, are used [1]. For further information, see [1], [31–33], [34].

The use of specific metal oxide catalysts allows isobutyraldehyde to be oxidized at high temperature directly to methacrolein, or methacrylic acid, or a mixture of the two [1], [35–38]. By variation of the reaction conditions, acetone or isopropyl alcohol is accessible [1], [39]. *n*-Butyric anhydride is also produced by oxidation of *n*-butyraldehyde [1].

Addition and Condensation Reactions. In a large number of addition and condensation reactions butyraldehydes react with themselves or other carbonyl compounds, amines, alcohols, nitriles, and other functional groups. On an industrial scale, the most important synthesis of this kind is the homocondensation of *n*-butyraldehyde in the presence of a basic catalyst. The initially formed 2-ethylhexenal is converted by hydrogenation to 2-ethylhexanol, the alcohol component of the most important PVC plasticizer, dioctyl phthalate (DOP) [1], [3–5], [40], [41]. Mild reaction conditions during the aldolization step allow butyraldol (2-ethyl-3-hydroxyhexanal) to be isolated, which can be hydrogenated to 2-ethyl-1,3-hexanediol.

The condensation product of *n*-butyraldehyde, 2-ethylhexenal, also is selectively hydrogenated in the presence of a precious metal catalyst to yield 2-ethylhexanal, which is converted to 2-ethylhexanoic acid or 2-ethylhexylamine [1], [3–5], [40].

Condensation of *n*-butyraldehyde with two moles of formaldehyde and subsequent hydrogenation yields trimethylolpropane [1], [42], [43]. Phenol and *n*-butyraldehyde condense to

Figure 1. Reactions of butyraldehydes

yield oil-soluble paints, and condensation products with urea are used in alcohol-soluble paints [1].

Condensation of *n*-butyraldehyde with acetaldehyde gives 2-ethylbutyl products [44]; their properties and applications are described in [45].

With poly(vinyl alcohol) *n*-butyraldehyde condenses to poly(vinyl butyral), PVB, which is used in the manufacture of laminated safety glass or as a bonding agent in paints [1].

Condensation products of *n*-butyraldehyde with aniline, butylamine, thiourea, diphenylguanidine, or methylthiocarbamate are used on a large scale as vulcanizing accelerators for rubber [1].

Reductive amination, that is, the reaction with hydrogen and ammonia or amines, provides access to primary, secondary, and tertiary butylamines [1], [46–48].

The homocondensation of isobutyraldehyde leads via the intermediate isobutyraldoxane (4-hydroxy-5,5-dimethyl-2,6-diisopropyl-1,3-dioxane) to isobutyraldol or secondary products such as 2,2,4-trimethylpentane-1,3-diol, 2,2,4-trimethylpentane-1,3-diol mono- and diisobutyrate, and 2,2,4-trimethylpentane-1-ol [1], [49–52].

The reaction of isobutyraldehyde with formaldehyde forms primary hydroxypivalaldehyde, a starting material for products with a neopentyl backbone. Especially neopentyl glycol, obtained by hydrogenation of hydroxypivalaldehyde, has become increasingly important [53], [54]. The wide variety of its uses is described in [55].

D,L-Hydroxy-β,β-dimethylbutyrolactone (pantolactone), is obtained by reaction of isobutyraldehyde, formaldehyde, and sodium cyanide [1], [56], [57].

The reaction of isobutyraldehyde with urea produces slow-release fertilizers (→ Fertilizers, Chap. 4.4.2.2.) [1]. Isobutyraldehyde serves as a

raw material for the syntheses of the amino acids D,L-valine and D,L-leucine [1].

The Tishchenko reaction is used to obtain isobutyl isobutyrate, a specialty solvent. Acetals of the butyraldehydes with various alcohols serve as solvents for cellulose, resins, and rubber [1], [54].

The crossed Tishchenko reaction of *n*-butyraldehyde with acetaldehyde provides commercial ester mixtures. Butyraldehydes and hydroxylamine yield the corresponding aldoximes or their salts [1], [54].

Other Reactions. Isobutyraldehyde can be isomerized to *n*-butyraldehyde and methyl ethyl ketone or converted to diisopropyl ketone [1], [54]. The chlorination of butyraldehydes yields fragrances and pharmaceutical intermediates [1], [54], [58–60]. *n*-Butyraldehyde is used as a catalyst component for special polymerization reactions [61–64]. Isobutyraldehyde can be converted to isobutene on special molybdenum catalysts [65].

Additional reactions and applications can be found in [1], [54] and references therein.

7. Toxicology

Butyraldehydes have low acute toxicity (Table 5). Exposure limits have not yet been established. Butyraldehyde liquids and vapors strongly irritate the skin, eyes, and respiratory organs, possible due to rapid oxidation to the carboxylic acids on contact with air. The symptoms are coughing, watering eyes, and a burning sensation on the skin and in the nose and throat. On exposure to higher doses, the CNS is impaired, resulting in depression, dizziness, headaches, and a slight narcotic effect. The repugnant smell of butyraldehydes occasionally causes nausea and vomiting. Subcutaneous injection of *n*-butyraldehyde causes hemolysis.

1. 1,4-Diols

1.1. 2-Butyne-1,4-diol

Physical Properties. 2-Butyne-1,4-diol [*110-65-6*], $HOCH_2-C{\equiv}C-CH_2OH$, M_r 86.09, *mp* 58 °C, *bp* 150 °C (at 1.8 kPa), is a colorless, hygroscopic, orthorhombic crystalline compound, which is readily soluble in water (374 g in 100 g at 25 °C) and in strongly polar solvents, e.g., alcohol, acetone, but only slightly soluble in ether and almost insoluble in hydrocarbons.

Heat of vaporization	50.28 kJ/mol, 584 kJ/kg (at 101.3 kPa)
Heat of combustion	2204 kJ/mol, 25.5 kJ/g
Flash point (DIN 51758)	152 °C
Ignition point	335 °C

Chemical Properties. 2-Butyne-1,4-diol decomposes relatively slowly between 160 and 200 °C, but at temperatures significantly above 200 °C violent decomposition can occur. Explosive decomposition can be caused or accelerated by alkali hydroxide, strong anhydrous acids, and certain heavy-metal salts, particularly those of mercury. 2-Butyne-1,4-diol is sensitive to oxidation.

Substitution of the hydroxyl groups is analogous to that of other diols. In the case of substitution by halogens very reactive compounds are formed. The reaction with bifunctional compounds leads to linear polymers only. The carbon – carbon triple bond undergoes the usual addition reactions of acetylene. Two moles of chlorine, but only one mole of bromine or iodine, are added per mole of diol. Chlorination in the presence of hydrochloric acid gives 2,3-dichloro-3-formylacrylic acid (mucochloric acid) [*87-56-9*]:

The addition of water, catalyzed by mercury salts, leads to the rather unstable 2-oxobutanediol.

Production. The synthesis of 2-butyne-1,4-diol, based on the work of Reppe and his coworkers [1–3], is carried out by reaction under pressure of acetylene and an aqueous solution of formaldehyde, catalyzed by copper acetylide:

$$2\,CH_2O + HC{\equiv}CH \longrightarrow HOCH_2-C{\equiv}C-CH_2OH \quad \Delta H = -100.5\ \text{kJ/mol}$$

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a04_455

This reversible reaction proceeds via propargyl alcohol, 2-propyn-1-ol [*107-19-7*], which mostly remains on the catalyst and thus only-partially goes into solution. The reaction is first order in respect to formaldehyde and, in industrial processes, effectively zero order in respect to acetylene.

The prime objective in the synthesis is to minimize the formaldehyde concentration in the resulting butynediol solutions. In principle, it is possible to react rather concentrated formaldehyde solutions partially, distill off the unreacted formaldehyde under pressure, and reintroduce it into the reactor. However, this process is complex and detrimental to the catalyst. Usually, the production of the butynediol is carried out continuously in cascades of three to five reactors. In these reactors the catalyst is present either as a fixed bed of strands 3 – 5 mm in diameter and 10 mm in length (Fig. 1) or as a fluidized bed of particles of diameter 0.1 – 2 mm. In the first case the formaldehyde solution, together with gaseous acetylene, is fed from the top [4]. In the fluidized-bed process the required amount of acetylene is dissolved in the solution and the solution is then fed from the bottom, suspending the catalyst (Fig. 2) [5].

Figure 1. Synthesis of butynediol, fixed-bed reactor
a) Liquid seal pump; b) Cooler; c) Reactor; d) Recycle pump; e) Gas – liquid separator

In either case the reactors are equipped with liquid-circulating systems. In the fixed-bed process the volume of the liquid is determined by external cooling. In the fluidized-bed process the volume of the circulating liquid is determined by the amount of acetylene which is introduced by absorbing columns or injectors.

The catalyst is 3 – 6 % bismuth(III) oxide and 10 – 20 % copper(II) oxide mostly supported on silica. Copper(II) oxide is converted by acetylene and formaldehyde at 60 – 90 °C to copper(I) acetylide, which complexes further acetylene [6] and thus forms the catalyst proper. Bismuth oxide inhibits the formation of water-insoluble polymers, the "cuprenes", from oligomeric acetylene complexes. Conditions of synthesis: 80 – 100 °C; 30 – 50 % aqueous formaldehyde solution; partial pressure of acetylene 2 – 6 bar, pH 5 – 8. Dilute alkali is added to the cycle solution to adjust the pH.

Figure 2. Synthesis of butynediol, fluidized-bed reactor
a) Liquid seal pump; b) Recycle pump; c) Air cooler; d) Reactor

The product solution contains 33 – 55 % butynediol, 1 – 2 % propargyl alcohol, 0.4 – 1 % unreacted formaldehyde, and 1 – 2 % byproducts. These byproducts are mainly high-boiling materials, along with some sodium formate. The butynediol can be recovered from this solution by vacuum distillation; the propargyl alcohol is recovered in an azeotrope.

Handling of High-Pressure Acetylene. Acetylene can explode or even detonate if the pressure rises above 1.4 bar (→ Acetylene). In butynediol plants this deflagration is often ignited by copper acetylide that was accidentally deposited in the head space; if it dries up, it can explode even upon slight vibration. Because other sources of ignition can never be excluded special precautions are required when handling acetylene at pressures above 1.4 bar. When filling all equipment with metal packings and all pipes with bundles of thin tubes (max. diameter 12.5 mm) the transition from deflagration to detonation (50 – 100 fold increase in pressure) can be excluded. Explosion (10 – 12 fold increase in pressure), however, cannot completely be avoided; this is accounted for by planning a 12-fold pressure for the whole apparatus [1]. When planning such plants the technical rules

for handling acetylene [7] and the publication of SARGENT [8] are recommended.

Environmental Protection. The off-gas, which mainly consists of acetylene and other hydrocarbons, is burnt. Waste-water problems arise when regenerating the catalyst. The water used for rinsing is treated biologically after traces of catalyst have been deposited. Spent catalyst must always be wet. Copper and bismuth can be recovered from the catalyst by acid treatment.

Analysis. Because of the high boiling points and the instability of the compounds involved, GC analysis is of limited value only. The determination of byproducts by titration or by fractional distillation (and subsequent GC analysis of the fractions) is time consuming but more reliable.

Storage and Transportation. The storage temperature should be kept below 40 °C and storage times longer than a few months should be avoided because the butynediol flakes tend to set up.

Uses. Approximately 95 % of the butynediol is hydrogenated in aqueous solution to 1,4-butanediol and occasionally to 2-butene-1,4-diol. In addition, butynediol is an intermediate for the production of 3-chloro-2-butynyl *N*- (3-chlorophenyl)carbamate, a herbicide. Solvay reacts butynediol with alkylene oxides and obtains a flame retardant after subsequent addition of bromine to the triple bond. Considerable amounts of butynediol are added to electroplating baths (nickel and copper) as brightening agent. In steel inhibitor picklings, the diol acts as a corrosion inhibitor.

Commercial Products. Butynediol is traded as 34 % aqueous solution by GAF and BASF (Golpanol BOZ liquid or Korantin BH liquid with hexamethylenetetramine being added to the latter). The anhydrous product is also traded as flakes. Products containing residues (GAF) are 97 – 98 % pure. Distilled butynediol (BASF) is 99 % pure: Butynediol pure cryst., Korantin BH solid, Golpanol pure solid.

1.2. 2-Butene-1,4-diol

Physical Properties. 2-Butene-1,4-diol [*110-64-5*], $HOCH_2-CH{=}CH-CH_2OH$, $C_4H_8O_2$, M_r 88.1, *mp* 10 °C, *bp* 240 °C (at 1013 mbar), *bp* 140 °C (at 24 mbar), is a pale yellow liquid, which is soluble in water. The product should be distilled at reduced pressure because it deteriorates above 180 °C.

Specific heat capacity	2.71 J g^{-1} K^{-1}
Flash point	127 °C
Ignition temperature	335 °C

Vapor pressure

t, °C	110.4	123.7	140	171.3	240
p, mbar	4.4	9.6	24	101.7	1013

Chemical Properties. Butenediol undergoes the typical reactions of alcohols, such as ester formation with anhydrides or acid chlorides, substitution of the hydroxyl groups by halogen, and the formation of polyesters with dicarboxylic acids. Typical reactions of the double bond are addition of halogen, epoxidation with hydrogen peroxide, copolymerization with vinyl esters, and the classic Diels-Alder reaction with dienes, e.g., with hexachlorocyclopentadiene.

Production. 2-Butene-1,4-diol is produced industrially by partial hydrogenation of 2-butyne-1,4-diol in aqueous solution and in the presence of a palladium catalyst, which generally is poisoned with zinc or other metals [9]. The main product of this synthesis is *cis*-2-butene-1,4-diol. Raney nickel can also be used as a catalyst for the hydrogenation [10]. Another method for the production of 2-butene-1,4-diol is the acetoxylation of butadiene followed by hydrolysis [11].

Analysis. The 2-butene-1,4-diol concentration in the product is determined by gas chromatography, the water content by the Karl Fischer method.

Storage and Quality. 2-Butene-1,4-diol must be stored in rust-free containers. Typical commercial specifications are: purity 98.5 %, *mp* 10 °C, color light to slightly yellow, water content < 0.5 %.

Uses. 2-Butene-1,4-diol is used for the production of endosulfan, chlorinated bicyclo-[2.2.1]heptene-(2)-bis(oxyalkylene-5,6) sulfite, an insecticide [12]; for the production of pyridoxine (vitamin B6) [13]; and in mixtures with other compounds as bactericide.

Economic Aspects. Worldwide 4000 – 5000 t/a of 2-butene-1,4-diol are produced, most of which is used for the production of crop protection products and vitamins.

1.3. 1,4-Butanediol

Physical Properties. 1,4-Butanediol [*110-63-4*], $HOCH_2CH_2CH_2CH_2OH$, $C_4H_{10}O_2$, M_r 90.12, is a colorless, almost odorless, hygroscopic liquid (see Table 1), readily soluble in water, alcohols, ketones, glycol ethers, and glycol ether acetates, less soluble in diethyl ether and esters, and not miscible with aliphatic and aromatic hydrocarbons and chlorinated hydrocarbons.

Chemical Properties. 1,4-Butanediol is readily cyclized in acid medium to give tetrahydrofuran. Dehydrogenation in the presence of copper – zinc – aluminum catalysts gives butyrolactone.

1,4-Butanediol reacts with monocarboxylic acids to give diesters [14]. Esterification with dicarboxylic acids and their derivatives leads to partially crystalline, linear, thermoplastic polymeric esters [15], [16].

At ca. 200 °C, 1,4-butanediol reacts with ammonia or an amine over nickel or cobalt catalysts and in the presence of hydrogen to give pyrrolidine or pyrrolidine derivatives [17], [18]. Phosgene reacts with 1,4-butanediol at −5 °C to give the bis(chloroformate) of butanediol [19], [20]. Acrylonitrile adds to 1,4-butanediol at 20 – 100 °C and in the presence of catalytic amounts of alkali to give 1,4-bis(2-cyanoethoxy)butane [21]. Like other alcohols, 1,4-butanediol can be vinylated, giving the divinyl ether [22].

Production. 1,4-Butanediol is made on a large industrial scale by continuous hydrogenation of the 2-butyne-1,4-diol [23] over modified nickel catalysts [24], [25]. The one-stage flow process is carried out at 80 – 160 °C and 300 bar according to Figure 3.

Figure 3. Hydrogenation of 2-butyne-1,4-diol
a) Piston pump; b) Preheater; c) Hydrogenation reactor; d) Gas – liquid separator; e) Recycle compressor; f) Canned motor pump; g) Hydrogen compressor; h) Air cooler

An aqueous solution of 2-butyne-1,4-diol (30 – 50 %), together with carbon monoxide-free hydrogen and recycled reaction mixture, which acts as medium for dissipation of heat, is lead over a reduced nickel – copper – manganese catalysts on silica gel strands. The initial temperature in the reactor is 80 °C; the temperature must not exceed 170 °C. In order to obtain a better distribution of the liquid, hydrogen is also circulated.

The raw product contains methanol, propanol, and butanol as byproducts as well as traces of 2-methyl-1,4-butanediol, hydroxybutyraldehyde, acetals, and triols. The reactor effluent is worked up to pure 1,4-butanediol by fractional distillation [26].

The hydrogenation of butynediol can also be carried out in two process steps. In the first stage, for example, at 40 bar, mainly 2-butene-1,4-diol is obtained, which is then completely hydrogenated at 300 bar in the second stage.

A further variant is the low-pressure hydrogenation at ca. 20 bar over a suspended Raney nickel catalyst, followed by hydrogenation at 120 – 140 °C and 140 – 210 bar on a fixed-bed contact [24].

Other Processes. 1,4-Butanediol can also be made from raw materials other than acetylene. Allyl alcohol and synthesis gas ($CO + H_2$) can

be converted to 1,4-butanediol according to a process invented by Daicel [27], [28].

Mitsubishi uses a three-step process [29], [30]: (1) the catalytic reaction of butadiene and acetic acid yields 1,4-diacetoxy-2-butene [*18621-75-5*]; (2) subsequenthydrogenation gives 1,4-diacetoxybutane; and (3) hydrolysis leads to 1,4-butanediol:

$$CH_2{=}CH{-}CH{=}CH_2 + 2\,CH_3COOH + 1/2\,O_2 \longrightarrow CH_3OOC{-}CH_2{-}CH{=}CH{-}CH_2{-}COOCH_3$$

$$\xrightarrow{H_2} \xrightarrow{H_2O} 2\,CH_3COOH + HO{-}CH_2CH_2CH_2CH_2{-}OH$$

BASF also has patented a similar process, in which acetic acid first adds to butadiene; the product then isomerizes to 1,4-diacetoxy-2-butene [31], [32].

According to a process practiced by Toyo Soda [33] chlorine first adds to butadiene to form a mixture of 1,4-dichloro-2-butene [*764-41-0*] and 3,4-dichloro-1-butene [*760-23-6*]. This mixturereacts with sodium acetate to form 1,4-diacetoxy-2-butene, which is subsequentlyhydrogenated directly to 1,4-butanediol.

In a patent described by Shell butadiene reacts with a peroxide to diperoxybutene, which is then converted to 1,4-butanediol by hydrogenation [34].

1,4-Butanediol also is a starting material for the production of *tetrahydrofuran* [*109-99-9*], which can be madedirectly from butadiene according to a process developed by Chevron [35]: 1,2-epoxy-3-butene is made from butadiene and a peroxide and subsequent isomerization yields 2,5-dihydrofuran [*1708-29-8*], whichis hydrogenated to tetrahydrofuran:

Other products derived from 1,4-butanediol are butyrolactone and tetrahydrofuran. In addition, both 1,4-butanediol and its derivatives are used in the textile, leather, photographic, food, and pharmaceutical industries.

The worldwide capacity for 1,4-butanediol is ca. 512 000 t/a in 1995. European producers are BASF and GAF/Chemische Werke Hüls; producers in the United States are Du Pont, GAF, and BASF Wyandotte. Whereas all these producers use acetylene as starting material, a plant at Mitsubishi Chemical Industries has been making 1,4-butanediol from butadiene since 1982.

Storage and Quality. 1,4-Butanediol can be stored indefinitely. The product is noncorrosive and therefore can be transported in cast iron containers. When it is stored for longer periods, storage tanks of steel or aluminum are necessary in order to avoid traces of iron in the product. In

this case, a cover of dry nitrogen also is recommended. Typical commercial specifications are: purity 99.5 – 99.8 %, *mp* 19.9 – 20.0 °C.

Uses and Economic Aspects. 1,4-Butanediol is a versatile intermediate for the chemical industry. The most important area of application is the production of polyurethanes and poly(butylene terephthalate), → Polyurethanes. Among the polyurethanes produced from 1,4-butanediol, cellular and compact elastomers are of prime importance. Poly(butylene terephthalate) is processed particularly to plastic materials and hot-melt adhesives, but is used also for the production of plastic films and fibers.

2. Other Butanediols

2.1. 2,3-Butanediol

2,3-Butanediol [*513-85-9*], 2,3-butylene glycol, exists in three stereoisomericforms:

Previously, 2,3-butanediol was obtained by bacterial fermentation of hexoses and pentoses. By pyrolysis of the diacetate very pure butadiene can be obtained, which has been used in the

optically inactive

United States for the production of synthetic rubber. Today butenes from crack gases are the raw material.

Physical Properties. The 2,3-butanediols, $C_4H_{10}O_2$, M_r 90.12, are colorless and odorless, strongly hygroscopic, oily liquids or crystals with a sweet taste. They are miscible with water and easily soluble in low molecular mass alcohols and ketones. For further physical data, see Table 2.

Chemical Properties [36]. The dehydrogenation of 2,3-butanediol yields acetoin [*513-86-0*] and diacetyl [*431-03-8*]. Dehydration leads chiefly to 2-butanone. The oxidation, e.g., with periodate, gives acetaldehyde; the reaction can be used for analytical determination. 2,3-Butanediol forms cyclic esters, acetals, and ketals. With diisocyanates, polyurethanes are obtained.

Production. After removal of butadiene and isobutene from crack gases, a C_4 hydrocarbon fraction, called C_4 raffinate II, is obtained, which contains approximately 77 % butenes and 23 % of a mixture of butane and isobutane. By chlorohydrination of this fraction with a solution of chlorine in water and subsequent cyclization of the chlorohydrins with sodium hydroxide, a butene oxide mixture of the following composition is obtained:

55 % *trans*-2,3-butene oxide, 30 % *cis*-2,3-butene oxide, 15 % 1,2-butene oxide.

Hydrolysis of this mixture (50 bar, 160 – 220 °C, reaction enthalpy $\Delta H = -42$ kJ/mol) yields a mixture of butanediols which are separated by vacuum fractionation. In order to avoid the formation of polyethers during the hydrolysis, an excess of water must be used. The fractionation of the butanediols is easier than that of the butene oxides. By this reaction sequence, *meso*-2,3-butanediol is obtained from *trans*-2-butene via *trans*-2,3-butene oxide; the racemic mixture of *R,R*- and *S,S*-2,3-butanediol is formed analogously from *cis*-2-butene via *cis*-2,3-butene oxide. For a discussion of stereochemistry of this reaction, see also [37].

Analysis, Storage. The butanediol mixture is analyzed best by GC (polyethylene glycol as stationary phase).

Storage and transportation do not provide any problems. However, the hygroscopicity of the product requires some precautions.

Uses. 2,3-Butanediol (at least 80 % meso isomer, the rest racemic mixture) is used as a cross-linking agent for naphthalene-1,5-diisocyanate

∗ Theoretically *bp* and absolute amount of rotation of enantiomers should be the same.

in the production of specific hard-rubber products (Vulkollan). Derivatives of 2,3-butanediol are important as insecticides (Sapecron: acetal with *N*-methylcarbamate of salicylic aldehyde) and as intermediates in the pharmaceutical industry. 2,3-Butanediols have some interest as humectants and in the synthesis of polymers and plasticizers.

2.2. 1,3-Butanediol

1,3-Butanediol [*107-88-0*], M_r 90.12, *bp* 207.5 °C (at 1013 mbar), *bp* 103 – 104 °C (at 10 mbar), d_4^{20} 1.0053, n_D^{20} 1.4410, is miscible with water and ethanol. The molecule has one center of chirality, and the data given above refer to the racemate. (*R*)-(−)-1,3-Butanediol [*6290-03-5*] has a specific rotation (ethanol) of $[\alpha]_D^{25} = -18.8°$.

1,3-Butanediol is produced as an intermediate in the manufacture of butadiene from acetaldol (→ Butadiene). This process has, however, been abandoned by most companies. The compound is mainly used as a component of special polyester resins.

2.3. 1,2-Butanediol [38]

Physical Properties. 1,2-Butanediol [*584-03-2*], $C_4H_{10}O_2$, M_r 90.12, *mp* −50 °C, *bp* 195 – 196.9 °C (at 101.3 kPa), is a colorless liquid, d_4^{20} 1.0023, n_D^{20} 1.4382. The diol is miscible with water in all proportions, readily soluble in alcohols, slightly soluble in ethers and esters, and insoluble in hydrocarbons. The dynamic viscosity at 20 °C is 73 mPa · s and the flash point 107 °C.

Chemical Properties. 1,2-Butanediol is a typical glycol and readily forms acetals and ketals; with dicarboxylic acids or anhydrides polyesters are formed and with diisocyanates polyurethanes.

Production. 1,2-Butanediol is synthesized by addition of water to 1,2-epoxybutane [*106-88-7*]:

The hydration reaction is exothermic (ΔH= −93 kJ/mol). A 10 to 20-fold molar excess of water is used to suppress polyether formation. The reaction is carried out either without a catalyst at 160 – 220 °C and 10 – 30 bar or in the presence of catalysts below 160 °C and only slightly above atmospheric pressure. Sulfuric acid or strongly acid ion exchange resins are used as catalysts [38]. Depending on the excess of water, selectivity is 70 – 92 %. Higher ethers of 1,2-butanediol are formed as byproducts.

Uses. The field of application for 1,2-butanediol is not very broad. It is used mainly as a solvent and intermediate.

3. Toxicology

1,2-Butanediol and 1,3-Butanediol. The median lethal dose (LD_{50}) of 1,2-butanediol is 16 g/kg (rat, oral) [39]; the corresponding value of 1,3-butanediol is 29.6 g/kg [40], [41]. Repeated administration of 1,3-butanediol to rats

(2 a, 10 wt % in the feed) and to dogs (2 a, 3 wt % in the feed) did not reveal any toxic effects [42]. In high doses, 1,3-butanediol has a narcotic effect with a specific depressive effect on the central nervous system [43], [44]. 1,3-Butanediol is approved as a food additive by the U.S. Food and Drug Administration [45].

2,3-Butanediol has an LD_{50} value of 8.9 g/kg (mouse, oral) [40].

1,4-Butanediol, however, with an LD_{50} value of 1.78 g/kg [39] or 1.5 g/kg [46] (both rat, oral) should be classified as harmful according to the EC Council Directive. The observed depressive effect on the central nervous system is attributed to the metabolite γ-hydroxybutyric acid.

None of the butanediol isomers either irritate or sensitize the skin; however, they cause strong (1,2-butanediol) to slight (1,3- and 1,4-butanediol) eye irritation [39].

2-Butene-1,4-diol with an LD_{50} value of about 860 mg/kg (rat, oral) is harmful. Eye and skin irritation are not observed, even after prolonged contact. Rats could inhale air saturated with 2-butene-1,4-diol at 20 °C for 8 h without showing any symptoms [46]. Repeated intake by rats (5 % in the feed) led to death after 7 – 11 days; 30 % in the feed led to the animals' death after four days [47].

1-Butene-3,4-diol with an LD_{50} value of approximately 1.5 g/kg (rat, oral) is also harmful. An 8-h inhalation of air saturated with the compound at 20 °C by rats does not lead to any effects. The animals' skin was not irritated after contact for several hours; however, irritation to the eyes may occur.

2-Butyne-1,4-diol is to be classified as "toxic" having an LD_{50} value of about 100 mg/kg (rat, oral). Strong irritation to the skin – especially after contact for several hours – and to the eyes were observed. An 8-h inhalation of air saturated with the compound at 20 °C by rats did not lead to any adverse effects [46].

Neither TLV nor MAK values have been established for the compounds cited above.

1. Introduction

Butanols (butyl alcohols) are aliphatic saturated C_4 alcohols (C_4H_9OH, M_r 74.12). There are four structural isomers of the alcohols: two primary, one secondary, and one tertiary; as there is an asymmetric C atom in the secondary alcohol, there are two stereoisomers of 2-butanol.

Formula	Nomenclature	Common name
$CH_3CH_2CH_2CH_2OH$	1-butanol [*71-36-3*]	*n*-butanol
$CH_3CH(CH_3)CH_2OH$	2-methyl-1-propanol [*78-83-1*]	isobutanol
$CH_3CH_2\overset{*}{C}H(OH)CH_3$	2-butanol [*78-92-2*]	*sec*-butanol
$CH_3-C(CH_3)_2-OH$	2-methyl-2-propanol [*75-65-0*]	*tert*-butanol

In addition to the systematic IUPAC nomenclature, other, nonsystematic names for the various butanols are in common use.

1-Butanol (*n*-butanol) occurs in nature in compound form. It also occurs, sometimes in high concentrations, in fusel oils obtained by fermentation. The first industrial production of 1-butanol, around 1912, was based on the discovery of the bacterium *Clostridium acetobutylicum Weizmann,* which causes carbohydrates to ferment to give mainly acetone and 1-butanol.

The continually increasing demand for 1-butanol could only be met by developing new manufacturing processes, such as the hydrogenation of crotonaldehyde formed by the aldolization of acetaldehyde; the Reppe synthesis (propylene carbonylation); and, in particular, the process by which most 1-butanol is produced, the hydrogenation of *n*-butyraldehyde, easily obtainable by the hydroformylation of propylene.

2-Methyl-1-propanol (isobutanol) occurs in natural products as well as in fusel oils (74 % of the total alcohol in the product of molasses fermentation), from which it can be isolated. The isobutyl oil synthesis, a reaction related to methanol synthesis from CO and H_2, first made it possible to produce larger quantities of 2-methyl-1-propanol. In the 1980s, nearly all 2-methyl-1-propanol is produced by the oxo synthesis (propylene hydroformylation). This straight forward production process and the attractive prices have led to a considerable expansion of the market for isobutanol.

The secondary and tertiary butanols are obtained by hydration of the corresponding unsaturated hydrocarbons, the butenes, whereas dehydration of the butanol yields the corresponding butene.

Thus, 2-butanol (*sec*-butanol), the simplest alcohol with an asymmetric carbon atom, can be obtained by the acid-catalyzed hydration

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a04_463

of 1- and 2-butene whereas hydration of 2-methylpropene (isobutene) yields 2-methyl-2-propanol (*tert*-butanol). The ready availability of 1- and 2-butene and 2-methylpropene from olefins derived from petroleum cracking has made the commercial application of these reactions possible. Most 2-butanol produced is further processed to 2-butanone (methyl ethyl ketone).

The rapid development of 2-methyl-2-propyl methyl ether as an additive for low-lead gasolines has increased the availability of 2-methyl-2-propanol, from which it can be derived as by-product.

2. Physical Properties

With the exception of 2-methyl-2-propanol (*mp* 25.6 °C) butanols are colorless liquids. Butanols exhibit a characteristic odor; their vapors have an irritant effect on mucous membranes and a narcotic effect in higher concentrations.

All butanols are completely miscible with common organic solvents. Only 2-methyl-2-propanol is completely miscible with water. The major characteristic physical properties of butanols are compiled in Table 1.

See Chapter 6 for safety data, such as flash points, ignition temperatures, and lower explosive limits.

For further physical properties of butanols see also [1]. The thermodynamic properties of all butanols have been examined in detail; cf. [2], [3] for 1-butanol; [4] for 2-methyl-1-propanol; [5–7] for 2-butanol; [8], [9] for 2-methyl-2-propanol.

References [10–12] give an outline of liquid – vapor equilibria for the distillation of butanols. H. A. Rizk and N. Youssef [13] as well as G. E. Rajala and J. Crossley [14] have investigated the dielectric properties of butanol in detail. D. Davis [15] has set up nomograms for the densities of aqueous solutions of 1-butanol, 2-methyl-1-propanol, and 2-methyl-2-propanol.

Further physical properties of the systems comprising water with the various butanols have been described by several authors; cf. [16–18] for 1-butanol/water, [19], [20] for 2-butanol, and [21] for 2-methyl-2-propanol.

For the phase equilibria of the ternary systems isobutyraldehyde/2-methyl-1-propanol (isobutanol)/water and 2-butanol/2-methyl-2-propanol (*tert*-butanol)/water cf. [22] and [23].

Table 2 shows the composition of some binary azeotropic mixtures. For other azeotropes see [24–26].

3. Chemical Properties

The chemical properties of butanols are mainly those of primary, secondary, and tertiary alcohols. In particular the reactive primary alcohols serve as starting materials for a wide range of reactions. The following deserve special mention:

Dehydration. The catalytic dehydration of alcohols for the preparation of olefins is a well-established reaction [27]. Of the butanols 2-methyl-2-propanol (*tert*-butanol) undergoes this reaction most readily. Even with dilute sulfuric acid water is split off on warming, leading to the formation of very pure 2-methylpropene (isobutene) [*115-11-7*] [28]. As 2-methylpropene is readily obtainable from the C_4-fractions of olefins from cracked petroleum this reaction is no longer of industrial importance, however. See Chap. 4 for the manufacture of pure 2-methylpropene. The dehydration of 2-methyl-1-propanol (isobutanol) similarly leads to the formation of 2-methylpropene.

The dehydration of 2-methyl-1-propanol to 2-methylpropene is carried out in the presence of γ-Al_2O_3 catalyst at about 300 – 350 °C with practically quantitative conversion and a 2-methylpropene selectivity of over 90 %. In an analogous manner 1-butanol can be dehydrated to a mixture of 1-butene [*106-98-9*] and *cis*- and *trans*-2-butene [*624-64-6*], [*590-18-1*] [29], [30].

Selective dehydration of 1-butanol in mixtures with 2-methyl-1-propanol can be carried out with calcium zeolite molecular sieves [31], due to the difference in the spatial structure of the two butanols.

Also, at lower temperature dibutyl ether [*142-96-1*] can be formed from 1-butanol in the presence of dehydration catalysts [30]. The branched butanols show little tendency to undergo this reaction.

2-Methyl-2-propanol	cyclohexane	81.4	71.3	37.0

Oxidation. As primary and secondary alcohols 1-butanol, 2-methyl-1-propanol, and 2-butanol can be dehydrogenated to the corresponding carbonyl compounds. Dehydrogenation can be carried out even at low reaction temperatures with oxidizing agents such as manganese(IV) oxide in sulfuric acid, nitric acid, chromic acid, or selenium dioxide [32].

Even without oxidizing agents the use of suitable catalysts (e.g., Cu) at higher temperatures enables the alcohols to be dehydrogenated to aldehyde or ketone until the thermodynamic equilibrium has been established [33–36]. 2-Butanol dehydrogenates to 2-butanone (methyl ethyl ketone) [*78-93-3*] at about 350 °C [37].

As a tertiary alcohol 2-methyl-2-propanol cannot be selectively dehydrogenated; splitting

of the molecule occurs under extreme conditions.

Primary alcohols can be oxidized to carboxylic acids under other reaction conditions. In addition to the standard oxidizing agents, this oxidation can be accomplished by the reaction of the alcohol with alkali hydroxide at 275 °C. In this reaction, which is based on the observations of GUERBERT, the alkali salt of butyric acid [*107-92-6*] is formed together with hydrogen and 2-ethylhexanol [*104-76-7*] (cf. also [38]).

The Koch-Haaf reaction can be used to prepare trimethylacetic acid [*75-98-9*] from 2-methyl-1-propanol and 2-methyl-2-propanol by the addition of carbon monoxide in the presence of sulfuric acid [39]. With readily available 2-methyl-1-propanol (isobutanol) from the oxo synthesis, trimethylacetic acid can be obtained in 89 % yield [40].

Alkylation. Butanols can be employed in a wide variety of alkylation reactions. *N*-alkyl-, *N,N*-dialkyl-, or *N,N,N*-trialkylamines are obtainable with ammonia and amines. The use of isomeric mixtures of alcohols leads to the corresponding mixed amines. Ring alkylation of aromatic hydrocarbons proceeds with butanol in the presence of Friedel-Crafts catalysts [41].

Esterification. Butanols can be converted in the usual manner into butyl esters with inorganic and organic acids. The reaction is generally carried out in the presence of acid catalysts. In certain cases excess of acid which is to be esterified can serve as the catalyst. The rate of ester formation greatly depends on the structure of the carboxylic acid and of the alcohol. The primary butanols react more rapidly than 2-butanol, which in turn reacts more quickly than 2-methyl-2-propanol. For the formation of esters with acid chlorides and acid anhydrides, as well as other esterification processes, see [42].

4. Production

Of the many available processes for the preparation of butanols, the following have achieved industrial importance:

1-Butanol:

propylene hydroformylation (oxo synthesis)
Reppe synthesis
crotonaldehyde hydrogenation

2-Methyl-1-propanol:

propylene hydroformylation
catalytic hydrogenation of carbon monoxide
homologization reaction

2-Butanol:

n-butene hydration

2-Methyl-2-propanol:

2-methylpropene hydration
byproduct of propylene oxide and methyl *tert*-butyl ether production

Oxo Synthesis. The most important process for the manufacture of 1-butanol and 2-methyl-1-propanol is propylene hydroformylation with subsequent hydrogenation of the aldehydes formed.

In the oxo reaction (hydroformylation) carbon monoxide [*630-08-0*] and hydrogen [*1333-74-0*] are added to a carbon – carbon double bond in the liquid phase in the presence of catalysts (hydrocarbonyls or substituted hydrocarbonyls of Co, Rh, or Ru) (→ Oxo Synthesis) [43]. In the first reaction step aldehydes are formed with one more C-atom than the original olefins. For olefins with more than two C-atoms, isomeric aldehyde mixtures are normally obtained. In the case of propylene these consist of 1-butanal and 2-methylpropanal.

There are several variations of the hydroformylation process, the differences being in the reaction conditions (pressure, temperature) as well as the catalyst system used. The classic high-pressure process exclusively used until the beginning of the 1970s operates at pressures of 20 – 30 MPa (200 – 300 bar) CO/H_2 and temperatures of 100 – 180 °C. The catalyst is Co. It

leads to about 75 % 1-butanol and about 25 % 2-methyl-1-propanol.

The new process developments of the past few years have led to a clear shift in the range of products. The processes operating at relatively low pressures (1 – 5 MPa , 10 – 50 bar) use modified Rh-catalysts. The isomeric ratios achieved are about 92 : 8 [44] or 95 : 5 [45] 1-butanol to 2-methyl-1-propanol. However, by the use of unmodified Rh the percentage of 2-methyl-1-propanol can be increased to about 50 %. For details on the oxo synthesis and propylene hydroformylation see [25], [38], [46] and → Oxo Synthesis.

Catalytic hydrogenation of the aldehydes leads to the formation of the corresponding alcohols.

As only primary alcohols can be obtained via the oxo synthesis, it is not possible to produce 2-butanol and 2-methyl-2-propanol by this process.

Reppe Process. 1-Butanol and 2-methyl-1-propanol can also be produced on a commercial scale by the carbonylation of propylene [*115-07-1*] developed by Reppe. In this process, developed in 1942, [47], [48], olefins, carbon monoxide, and water are made to react under pressure in the presence of a catalyst (tertiary ammonium salt of polynuclear iron carbonyl hydrides). The difference between this process and the classic Co-catalyzed hydroformylation is that at low temperature (about 100 °C) and low pressure (0.5 – 2 MPa, 5 – 20 bar) alcohols are formed directly from the olefin.

As with the oxo synthesis the carbon monoxide can be added to both C-atoms of the double bond which means that, when propylene is used, 1-butanol and 2-methyl-1-propanol are obtained in a ratio of 86 : 14.

The catalyst is sensitive both to air and to higher temperatures at which, in the presence of water and CO_2, it decomposes into iron carbonate. To achieve adequate reaction rates the catalyst, carbonyl triferrate, must be present in concentrations of $\gg$ 10 % in the reaction solution; this is attained by the presence of dissolving agents (*N*-alkylpyrrolidine); see [49], [50], [51] for details of the process.

The Reppe process has not been as successful as propylene hydroformylation with Co catalysts despite favorable n/iso ratios in the reaction products and milder reaction conditions [52]. This can be attributed to the more expensive process technology.

Hydrogenation of Crotonaldehyde [*4170-30-3*]. Until the mid 1950s the manufacture of 1-butanol based on acetaldehyde was the preferred process. With the development of the oxo synthesis, however, it has lost its importance even in Japan and the USA and is no longer in use.

The individual steps of the process are as follows:

aldol condensation

$$2\,CH_3CHO \longrightarrow CH_3CH(OH)CH_2CHO$$

splitting off of water

$$CH_3CH(OH)CH_2CHO \longrightarrow CH_3CH=CHCHO + H_2O$$

hydrogenation

$$CH_3CH=CHCHO + 2\,H_2 \longrightarrow CH_3CH_2CH_2CH_2OH$$

Acetaldehyde is aldolized to acetaldol at normal temperature and pressure in the presence of alkaline catalysts. With conversions of about 60 % the acetaldol yield is about 95 %. Unreacted acetaldehyde can be distilled off and recycled. The removal of water and formation of aldehyde is brought about by acidification of the acetaldol with acetic acid or phosphoric acid and subsequent distillation, whereby the crotonaldehyde is obtained almost quantitatively as the top product.

Various gas- and liquid-phase processes have proved their value for the hydrogenation of crotonaldehyde to 1-butanol. Copper catalysts are particularly useful. About 1000 kg of 1-butanol can be obtained from 1350 kg of acetaldehyde [53].

The future economic importance of the crotonaldehyde hydrogenation process will depend to a large extent on developments in the raw materials market. As “crude oil” raw material becomes scarcer and more expensive as a basis

for the oxo synthesis, the alternative route based on ethanol from fermentation will become increasingly competitive. The biomass substrate for ethanol production is almost inexhaustible. The ethanol is first dehydrogenated to form acetaldehyde, from which the synthesis can proceed.

Such a process route is an increasingly interesting alternative for tropical countries with large supplies of cheap biomass as well as for the more developed countries of the third world which do not have their own oil resources [54].

Catalytic Hydrogenation of Carbon Monoxide. In addition to the CO/H_2-based methanol synthesis developed commercially in the 1920s, other analogous processes were developed for the manufacture of higher alcohols. Compared with the methanol synthesis, however, these processes found only limited application. Nowadays they have no commercial importance.

The most significant process for the production of 2-methyl-1-propanol was the BASF isobutanol oil synthesis. Reaction products with about 50 % methanol [*67-56-1*] and 11 – 14 % 2-methyl-1-propanol as well as various other components were obtained from CO and H_2 at temperatures of about 430 °C and pressures of about 30 MPa (300 bar) in the presence of a KOH-modified methanol synthesis catalyst [55], [56]. BASF ceased its isobutyl oil synthesis in 1952 when 2-methyl-1-propanol and its secondary product 2-methylpropene could be obtained more economically using the oxo synthesis or via a petrochemical route. Further comprehensive experiments to obtain the desired butanol from the cheap raw materials methanol and ethanol with the homologization reaction have so far proved fruitless. Butanols have so far only been obtained in small amounts as byproducts. A review is given in [57].

Olefin Hydration. 2-Butanol (*sec*-butanol) and 2-methyl-2-propanol (*tert*-butanol) can be obtained by the acid-catalyzed addition of water to 1- or 2-butene [*106-98-9*], [*107-01-7*] and 2-methylpropene [*115-11-7*] respectively. The water adds at the double bond in accordance with the Markovnikov rule. The difference in olefin reactivity can be used for the selective manufacture of 2-butanol or 2-methyl-2-propanol from technical C_4-fractions where the two alcohols are prepared in turn and isolated. 2-Methylpropene can be completely converted to 2-methyl-1-propanol with 65 % sulfuric acid. Hydration of *n*-butene, on the other hand, requires 75 – 80 % H_2SO_4 [58]. Because of the tendency of the olefins to polymerize readily, the requisite reaction temperatures must not be exceeded.

In addition to this indirect hydration another process variant is known to industry in which the olefins are hydrated directly at elevated temperatures (about 200 – 300 °C) and higher pressures (10 – 35 MPa, 100 – 350 bar) [59], [60].

$$CH_3CH{=}CHCH_3 + H_2O \overset{\text{cat.}}{\rightleftharpoons} CH_3CH_2\underset{\underset{OH}{|}}{C}HCH_3$$

Various catalysts have been described for direct hydration, such as tungsten oxide [61] and aqueous aluminum hydroxide gel suspensions [62]. For the hydration of 1-butene and 2-butene the best results are obtained at temperatures between 220 and 300 °C or in the case of 2-methylpropene, at 190 – 245 °C [63]. Direct hydration of the olefins has not yet established itself as a serious competitor to indirect hydration. For process improvement see [64].

Other Processes. 2-Methyl-2-propanol (*tert*-butanol) is formed during the manufacture of propylene oxide from 2-methylpropane [*75-28-5*] in an amount of about 1.2 t per ton of propylene oxide [27, pp. 834, 1005]. In an intermediate stage *tert*-butyl hydroperoxide [*75-91-2*] is formed from isobutane. Another process, in which 2-methyl-2-propanol is obtained as a by-product, is the splitting of methyl *tert*-butyl ether to highly pure 2-methylpropene or 2-methyl-2-propanol. Similarly the methyl *tert*-butyl ether synthesis with slight traces of water in the feedstock (methanol and C_4-olefins) produces 2-methyl-2-propanol as a byproduct [65].

In the literature a number of other methods for the preparation of butanol are cited which are generally of no significance other than for laboratory preparation. A comprehensive review is to be found in B. Cornils and E. Zilly [38].

5. Quality Requirements and Control

On an industrial scale the four different butanols are generally marketed as pure substances and not as isomer mixtures. Because of their many applications both as commodities and as materials for the manufacture of special fine chemicals a high standard of purity is demanded for the butanols.

The quality is mainly controlled by determining the physical and chemical properties of the alcohols, such as density, refractive index, color, water content, hydroxyl value, acid value, carbonyl value, and distillation range. The characteristic values are normally determined according to the ASTM [66], DIN [67], or the BS methods [68].

Table 3 lists the standard specifications which are stipulated by the American Society for Testing and Materials for 1-butanol, 2-butanol, and 2-methyl-1-propanol.

The B. S. I. (British Standards Institution) has issued specifications for 1-butanol (BS 508: 1966) and 2-butanol (BS 1993: 1968).

The best way to verify isomer purity and detect traces of impurities is by gas-chromatographic analysis. Such analyses can be carried out rapidly and with good reproducibility, on a routine basis, enabling the use of a high sampling frequency.

Separation can be effected by the use of both polar and non-polar packed columns or appropriate capillary columns.

For general purity analyses a thermal conductivity detector system is used; trace (impurity) analysis is carried out using a flame ionization detector system. Experience has shown that nitrogen, hydrogen, and helium are suitable carrier gases.

The degree of purity of commercial 1-butanol, 2-methyl-1-propanol, and 2-butanol is at least 99 wt %. 2-Methyl-2-propanol is supplied both as a product of at least 99.8 wt % purity and as an azeotropic mixture with 11 to 12 wt % water.

In addition to characteristic value determination and gas-chromatographic analysis a number of special analyses and tests may be carried out depending on the intended application, such as esterification tests with phthalic anhydride and color tests with concentrated sulfuric acid or $KMnO_4$.

6. Storage and Transportation

Butanols can be stored or dispatched in untreated mild steel or enamelled steel drums provided that ingress of moisture is prevented. Stainless steel containers are also suitable. The butanols are transported in rail and road tank cars, and in drums as well as in tanker vessels and containers. It is important to observe the national and international safety regulations relating to aviation, ocean-going and inland waterway shipping, rail and road transport as well as the particular safety requirements for butanols.

Some important data relating to the safe handling, storage, and transport of butanols are compiled in Table 4.

7. Uses

1-Butanol. 1-Butanol is used principally in the field of surface coating. In the USA, for instance, approx. 85 % of 1-butanol production finds an outlet in this sector of the market. It is used either directly as a solvent for varnishes or it is converted into derivatives which then serve as solvents or monomer components.

1-Butanol cannot be used directly as a solvent in the production of nitrocellulose lacquers; in admixture with toluene, ethanol, or various esters, however, it is an excellent thinner.

The addition of 5 – 10 % of 1-butanol is also valuable in overcoming "blushing" (unwanted white opacity) which may arise when large quantities of thinners, particularly volatile solvents, are used.

1-Butanol is also useful for regulating the viscosity and improving the flow properties of varnishes and for the prevention of "streaking" in paints and lacquers based on spirit-soluble gums and resins.

Although not itself a solvent for substances such as polystyrene and chlorinated rubber, 1-butanol can be successfully used in quantities up to 20 % as a diluent for the commonly used solvents for these substances, which are mainly the esters of the saturated carboxylic acids; in particular, the acetates.

The acrylic ester of 1-butanol has become increasingly important during the last decade.

Table 3. ASTM Specifications for butanols [66]

ASTM-Standard:	1-Butanol D 304-80	2-Methyl-1-propanol D 1719-81	2-Butanol D 1007-80	ASTM Standard
Sampling				D 268-80
Specific gravity	0.810 – 0.813	0.802 – 0.804	0.807 – 0.809	D 268-80
Color (platinum – cobalt scale)	< 10	< 10	< 10	D 1209
Distillation range	117.7 °C within a range of 1.5 °C	107.9 °C within a range of 2 °C	98.0 – 101.0 °C	D 1078
Nonvolatile matter	< 0.005 g/100 mL	< 0.005 g/100 mL	< 0.005 g/100 mL	D 1353
Odor	characteristic, nonresidual	characteristic, nonresidual	characteristic, nonresidual	D 1296
Water (Karl Fischer)	< 0.1 wt %	< 0.2 wt %	< 0.5 wt %	D 1364

[c] Time-weighted average concentration.

It has become an essential component of latex paints since such coatings are not only robust but can also be produced relatively cheaply. The 1-butyl esters of phthalic, adipic, sebacic, oleic, azelaic, stearic, and phosphoric acids are used as plasticizers and additives for surface coatings. The most important of these products is di-1-butyl phthalate (DBP). Consumption is, however, stagnating and in some countries it decreased slightly within the last years.

In the USA in particular, but also in the Federal Republic of Germany and Belgium, 1-butanol is used for the manufacture of butylamines.

1-Butanol has numerous applications in the plastics and textile sector. It is used as a coagulation bath for spinning acrylic fibers and in the dyeing of poly(vinyl alcohol) fibers.

2-Methyl-1-propanol. The fields of application of 2-methyl-1-propanol (isobutanol) closely resemble those of 1-butanol. Indeed, because of its lower price it can often replace 1-butanol and is accordingly used as a solvent, diluent, and additive for nitrocellulose and synthetic resins; wetting agent; cleaner additive; and component of printing inks and related products. Its capacity for dissolving resins (ketone, phthalate, urea, and melamine – formaldehyde resins) is of commercial importance. As a solvent for phenol – formaldehyde resins, however, 2-methyl-1-propanol is not as effective as 1-butanol.

Several esters exhibit excellent solvent properties; in particular, isobutyl acetate is a very good solvent for fats, chlorinated rubber, polystyrene, and coumarone resins. The esters of phthalic acid, adipic acid, some dicarboxylic acids as well as phosphoric acid are used as plasticizers, particularly for PVC and its copolymers and for cellulose derivatives.

The isobutyl esters of 2,4-dichloro- and 2,4,5-trichlorophenoxyacetic acid exhibit herbicidal activity. For the anti-freezing properties of 2-methyl-1-propanol in gasoline see [72].

Also of interest is the use of 2-methyl-1-propanol as an extracting agent in the recovery of ammonium phosphate [73].

2-Butanol. Practically all of the 2-butanol produced is dehydrogenated to 2-butanone (MEK or methyl ethyl ketone) which has found considerable application because of its good solvent properties and its favorable boiling point (79.57 °C). 2-Butanol itself is also used as a solvent: in particular, when mixed with aromatic hydrocarbons it is especially suitable as a solvent for alkyd resins and ethylcellulose lacquers. The ability of 2-butanol to dissolve both water and oils is applied in the manufacture of brake fluids and cleaning agents.

2-Butanol is converted into amines by treatment with ammonia. The acetate is recommended as a good solvent for nitrocellulose; the xanthate is used in ore flotation. 2-Butanol also finds application in the manufacture of perfumes, dyestuffs, fruit essences, and wetting agents.

2-Methyl-2-propanol. Consumption of 2-methyl-2-propanol is small in comparison with the other butanols, although its use appears to be growing. The solvent sector is again the major field of application. 2-Methyl-2-propanol is also used as an agent for introducing the *tert*-butyl group into organic compounds (e.g., *tert*-butylphenol for the preparation of oil-soluble resins and antioxidants, trinitro-*tert*-butyltoluene as artificial musk) and as a starting material for the preparation of peroxides (polymerization catalysts).

2-Methyl-2-propanol competes with 2-propanol as a gasoline additive to prevent carburetor freezing. The methylether can be used as an antiknock agent in gasoline. Its use as a fuel additive increased from 175 000 t in 1982 to 400 000 t in 1983.

8. Economic Aspects

Both in the industrialized countries and worldwide, there is considerable excess capacity for the manufacture of 1-butanol and 2-methyl-1-propanol, the two major products in this group of substances (Table 5).

Table 5. Butanol capacities in the leading producer countries in 1984

	1-Butanol/∗ 2-methyl-1-propanol, 1000 t	2-Butanol, 1000 t
United States	700	
F.R. of Germany	300	60
Western Europe		422 ∗∗
Japan	206	146

∗ Any 1-butanol production plant also can be used for the manufacture of 2-methyl-1-propanol;
∗∗ 1982

Plant utilization was approx. 60 – 70 % in 1983.

The uses can vary considerably from one region to another. As well as direct use as a sol vent the main areas of application are in plasticizers, butyl acetate, acrylic esters, and glycol esters (see Table 6).

Table 6. Butanol consumption by end use, %

	Japan (1982)	USA (1980)
Plasticizers	13	8
Solvents	18	17
Butyl acetate	20	9
Butyl acrylate	24	29
Glycol ethers and esters	13	23
Miscellaneous	12	14

9. Toxicology and Occupational Health [74–78]

The main effects of exposure to excessive concentrations of all butanols are irritation of the mucous membranes and depression of the central nervous system. Animal studies have shown low acute oral, dermal, and inhalation toxicity. There is insufficient data to make a reliable assessment of the long-term effects in animals. The limited amount of documented experience in humans suggests that excessive exposure can cause irritation, headache, nausea, fatigue, and dizziness.

9.1. 1-Butanol

The lowest median lethal dose (LD_{50}) published in the literature is 790 mg/kg (rat, oral) and 4200 mg/kg (rabbit, dermal) [74]. Inhalation of

high concentrations of 1-butanol by experimental animals results in pulmonary and eye irritation, incoordination, and narcosis. The lowest LC_{50} published in the literature is 8000 ppm (rats, inhal., 4 h) [74]. Application of drops of 1-butanol into the rabbit eye produces severe corneal irritation. 1-Butanol has a slight to moderate irritating effect on rabbit skin [75]. 1-Butanol was found to be non-mutagenic in the Ames test [75].

Conjunctivitis and keratitis, sometimes accompanied by small intracorneal vacuoles, were reported among workers exposed to 1-butanol vapors. Intracorneal vacuoles proved to be reversible after exposure had ceased [76]. In a ten-year-study, workers exposed to 1-butanol at concentrations of 200 ppm and above developed corneal inflammation associated with a burning sensation, blurring of the vision, lacrimation, and photophobia. The mean erythrocyte count was slightly lowered. There were only rare complaints of irritation when the concentration was 100 ppm [75].

Further data indicate that eye irritation may be expected when the concentration of 1-butanol is above 50 ppm [76]. According to another study humans exposed to 1-butanol showed mild irritation already at 25 ppm, followed by headaches at 50 ppm [77]. Workers exposed to 80 ppm experienced a greater hearing loss (hypoacusia) in comparison with an unexposed group [77]. Dermatitis of the fingers and hands upon exposure to 1-butanol is also reported [76].

Exposure limits:

TLV (ceiling limit) 50 ppm (skin) [77],
OSHA air standard (TWA) 100 ppm [74],
MAK value 100 ppm.

9.2. 2-Butanol

The lowest LD_{50} published in the literature is 4400 mg/kg (rat, oral) [77]. 2-Butanol, like the other butanols, is a depressant to the central nervous system. The lowest lethal concentration published in the literature is 10670 ppm for mice exposed for 225 min; repeated exposure of mice to 5330 ppm produced narcosis without death; and no acute signs of intoxication were observed in mice exposed to 1650 ppm for 420 min [75].

2-Butanol caused severe corneal injury when applied to the rabbit eye but was not found to be irritating to the rabbit skin [75].

According to one report industrial exposure to about 100 ppm has not resulted in any difficulties [77]. Another study concludes that irritation of the eyes, nose, and throat, headache, nausea, fatigue, and dizziness have been experienced from excessive exposure to 2-butanol [75].

Exposure limits:

TLV 100 ppm (TWA); 150 ppm (STEL) [77],
OSHA air standard 150 ppm (TWA),
MAK value 100 ppm.

9.3. 2-Methyl-1-propanol

The lowest published LD_{50} is 2460 mg/kg (rat, oral) [75]. A dermal LD_{50} of 4250 mg/kg in the rabbit indicates a low toxicity due to local application [75]. The lowest LC_{50} for 2-methyl-1-propanol is 8000 ppm (rats, inhal., 4 h) [77]. The compound produces narcosis in mice that had been intermittently exposed to 6400 ppm for a total of 136 h. The narcotic dosage is followed by slight organic changes in the liver and kidneys. Repeated exposure of mice to 2125 ppm for 9.25 h did not cause any adverse effect [76].

Application of 2-methyl-1-propanol to the rabbit eye causes moderate to severe irritation. A moderate irritation was observed after 24-h exposure of the rabbit skin [74].

The results of long-term studies in which a small number of rats received the material either orally or subcutaneously suggest that 2-methyl-1-propanol may have a carcinogenic potential [75]. Exposure of *E. coli* bacteria resulted in mutagenesis [74].

In humans, there was no evidence of eye irritation during repeated 8-h exposure to levels in the order of 100 ppm [75]. Industrial exposure to mixed vapors of butyl acetate and 2-methyl-1-propanol has caused vacuolar keratitis in several workers but it is not known which of the substances was responsible [76]. Application of 2-methyl-1-propanol to human skin resulted in slight erythema and hyperemia [76].

Exposure limits:

TLV 50 ppm (TWA), 75 ppm (STEL) [77], OSHA air standard 100 ppm (TWA) [74], MAK value 100 ppm.

9.4. 2-Methyl-2-propanol

The lowest LD_{50} is reported to be 3500 mg/kg (rat, oral) [74]. The acute effect of the bad-smelling 2-methyl-2-propanol is that of a narcotic. Prolonged contact with rabbit skin failed to cause irritation [75]. The testing of the compound by *NTP* (National Toxicology Programm, U.S. Department of Health and Human Services) for carcinogenesis bioassay began in June 1983 [74].

Following application to human skin there was no reaction other than slight erythema and hyperemia. Irritating effects, headache, nausea, fatigue, and dizziness are reported as symptoms of excessive exposure [75].

Exposure limits:

TLV 100 ppm (TWA), 150 ppm (STEL) [77], OSHA air standard 100 ppm (TWA) [74], MAK value 100 ppm.

1. Introduction

2-Butanone [*78-93-3*], methyl ethyl ketone, MEK, is the second link in the homologous series of aliphatic ketones and, next to acetone, the most important commercially produced ketone. 2-Butanone is produced primarily by dehydrogenation of 2-butanol, analogous to the production of acetone by dehydrogenation of gaseous isopropyl alcohol on copper, zinc, or bronze catalysts at 400 – 550 °C. At 80 – 95 % *sec*-butyl alcohol conversion, MEK selectivity is > 95 %. In some cases MEK can be produced in the same facilities as acetone. Butenes (dehydration) and higher ketones (autocondensation) are byproducts. In 1995, 730 000 t of MEK were produced worldwide.

2-Butanone is produced by ARCO (US), AKZO (NL), Biochimica (ES), BP (GB), Carbochlor (Argent.), Celanese (US, CA, Mexico), Esso (GB, US), Maruzen (JP), PCUK (FR), Shell (FR, NL, US, CA), Texaco (FRG), Tonen (JP), UCC (US), Sasol (ZA). Interest in MEK as a solvent for paints and adhesives has been growing since the 1980s. In general, MEK is considered to be a competitor for ethyl acetate, especially as a low-boiling solvent. It has broad application as a solvent for nitrocellulose, cellulose acetate – butyrate, ethylcellulose, acrylic resins, vinylacetates, and vinylchloride – vinylacetate copolymer (based on synthetic surface-coating preparation). It is favored as a lacquer solvent because of its low viscosity, high solids concentration, and great diluent tolerance.

Moreover, MEK can be used as an activator for oxidative reactions, as a selective extractant, as a special solvent for dewaxing mineral oil fractions, and as a chemical intermediate. (see Table 1).

2. Physical Properties

2-Butanone, methyl ethyl ketone, MEK, $CH_3COCH_2CH_3$, is a relatively mobile, colorless liquid. Its typical odor resembles that of acetone. The compound is only partially water-miscible, whereas it is completely miscible with most organic solvents. 2-Butanone forms binary and ternary azeotropic mixtures in combination with water and several other organic solvents (see Table 2).

Table 2. Binary azeotropic mixtures containing MEK [11]

Second component	Mass fraction of MEK	*bp* at 1013 hPa, °C
Water	88.7	73.4
Benzene	37.5	78.4
n-Hexane	29.5	64.3
n-Heptane	73.0	77.0
Cyclohexane	40	72
1,3-Cyclohexadiene	40	73
Methanol	30.0	63.5
Ethanol	60.9	74.0

Carbon disulfide	15.3	45.85
Propyl mercaptan	75	55.5
Thiophene	55.0	76.0
Ethyl sulfide	20	77.5

2-Butanone does not form a binary azeotropic mixture with toluene, *m*-xylene, *n*-butanol, isobutanol, *sec*-butyl alcohol, 4-methyl-2-pentanol, allyl alcohol, acetic acid methyl ester, acetic acid isopropyl ester, acetic acid *n*-butyl ester, acetic acid isobutyl ester, 1,1-dichloroethane, isobutyl chloride, propyl bromide, ethyl iodide, trichloroethylene, dichlorobromomethane, isobutyl bromide, formic acid, and acetic acid.

2-Butanone forms ternary azeotropes with water/benzene and water/carbon tetrachloride [11].

3. Chemical Properties

Under normal conditions and in the absence of atmospheric oxygen MEK is stable. Care must be taken after prolonged storage because peroxides may form in the presence of oxygen [12].

2-Butanone is unsaponifiable and, unlike esters, does not form corrosive products upon hydrolysis. It is heat and light stable. It decomposes only after prolonged UV exposure (yielding ethane, methane, carbon monoxide, ethylene, and diacetyl) [13].

Diacetyl [*431-03-8*] is formed by oxidation with airin the presence of special catalysts [14].

Methyl ethyl ketone peroxide [*19393-67-0*], a polymerization catalyst, is formed by oxidation with a 30 % solutionof hydrogen peroxide [15]. Nitric acid and other strong oxidants oxidize MEK to a mixture of formic and propionic acids [15].

sec-Butyl alcohol [*78-92-2*] is obtained by catalytic reduction with hydrogen [15]. It can also be formed by electrolytic reduction in sodium acetate solution or by reduction with ammonium amalgam or lithium aluminum hydride. 3,4-Dimethyl-3,4-hexanediol is obtained by electrolytic reduction in an acidic medium or by reduction with magnesium amalgam [15].

Methyl ethyl ketone forms addition products with hydrogen cyanide as well as with sodium and potassium hydrogen sulfites. In an alkaline medium MEK condenses with aldehydes to form higher unsaturated ketones. Condensation with formaldehyde to form methyl isopropenyl ketone [*563-80-4*], an intermediatefor further syntheses, is of particular interest. During base-catalyzed autocondensationin the liquid phase and during gase-phase condensation on alkalinized copper catalysts, the carbonyl group reacts with the methyl group, whereas during acid-catalyzed condensation the methylene group in α-position to the carbonyl group is attacked [16].

Methyl ethyl ketone and citral [*5392-40-5*] condense toform methylpseudoionone that can be cyclized to methylionone, a compound used for producing synthetic violet perfume.

During condensation with low-molecular aldehydes (during base-catalyzed and acid-catalyzed aldolization) the α-position of the carbonyl group is first occupied [17], [18].

Thus, the base-catalyzed aldolization with less than amounts of formaldehyde yields 2-methyl butane-1-ol-3-one [17] and exhaustive hydroxymethylation, with reduction of the carbonyl group (crossed Cannizzaro reaction), produces desoxyanhydroeneaheptite [19].

When MEK is reacted with primary and secondary alcohols, higher ketones are obtained. Reaction with *sec*-butyl alcohol gives ethyl amyl ketone [*106-68-3*] [20].

Methyl ethyl ketone reacts with polyoxy compounds or epoxides to form cyclic products.

Amyl nitrite [*110-46-3*] attacks the CH_2 groupin α-position to the carbonyl group and yields themonooxime of diacetyl.

The keto group reacts with amino groups with elimination of water. In combination with hydroxylamine [*7803-49-8*], methyl ethylketoxime, an antiskinning agent, is formed.

Condensation of MEK with aliphatic esters and anhydrides gives β-diketones.

Phenols react with MEK to form oxyphenylene compounds. In combination with phenol, 2,2-hydroxyphenyl butane is obtained, a homolog of hydroxyphenyl propane (Bisphenol A [*80-05-7*]), an important materialfor the production of synthetic resins.

Methyl ethyl ketone can be halogenated in the α-position. Methyl ethyl ketone reacts with Grignard compounds to form tertiary alcohols. With acetylene in the presence of sodium amide 3-methyl-1-pentyn-3-ol [*77-75-8*] is formed. *N*-Methyl-formyl-aminobutaneis obtained from MEK plus *N*-methylformamide. The Reformatzky reaction produces the β-oxyester from monobromine-substituted esters [20].

4. Production

Most MEK (88 %) is produced today by dehydrogenation of *sec*-butyl alcohol (SBA). SBA can easily be produced by hydration of *n*-butenes (from petrochemically produced C_4 raffinates) in a two-step process (catalyst: sulfuric acid), or in a single-step process by direct addition of water, acidic ion-exchange resins being used as a catalyst [21]. The remaining 12 % MEK is produced by processes in which liquid butane is catalytically oxidized, giving both acetic acid and MEK [22].

The direct oxidation of *n*-butenes (Hoechst-Wacker process, Maruzen process, [23], [24]) has not been generally accepted, because of undesired byproducts.

The *sec*-butylbenzenehydroperoxide route giving phenol and MEK by acid-catalyzed splitting [25] is uneconomical. The autoxidation of liquid *sec*-butyl alcohol, giving MEK and hydrogen peroxide [26], and the catalytic oxidative hydration of gaseous *n*-butenes [27] are also uneconomical. The oxidation of *n*-butenes with ethylbenzenehydroperoxide to form butylene oxides, and subsequent hydration and formation of ketones appears to be moderately attractive [28]. Styrene, *n*-butanol, and MEK are obtained in coupled production.

4.1. Catalytic Dehydrogenation of *sec*-Butyl Alcohol (SBA) in the Gaseous Phase

The catalytic dehydrogenation of SBA is an endothermic reaction (51 kJ/mol). The equilibrium constant for SBA can be calculated as follows [29]:

$$\log K_{\mathrm{p}} = -2.790 \times T^{-1} + 1.51 \log T + 1.865$$
$$(T = \text{reaction temperature, in K})$$

The MEK concentration in the reaction mixture increases with the temperature and reaches its maximum at approx. 350 °C [30].

Copper [31], zinc [32], or bronze [33] are used as catalysts in gas-phase dehydrogenation. The latter two require high dehydrogenation temperatures (400 °C). Dehydration of SBA to butenes takes place as a side reaction on

zinc oxide. Platinum on alumina [34], copper or chromium [35], [36] as well as copper, and zinc on alumina [34] are recommended as dehydrogenation catalysts for aqueous SBA.

Commercially used catalysts are reactivated by oxidation, after 3 to 6 months use. They have a life expectancy of several years. Catalyst life and alcohol conversion are impaired by contamination with water, butene oligomers, and di-*sec*-butyl ether [37].

Deutsche Texaco developed a process in which practically anhydrous *sec*-butyl alcohol has been produced since 1983 by direct hydration of *n*-butene, catalyzed by acidic ion-exchange resin; it is then dehydrogenated on a copper-based precipitating catalyst at 240 – 260 °C under normal pressure [21], [31]. The LHSV (4 L/L of catalyst · h), the conversion (90 – 95 %), and the catalyst life until reactivation becomes necessary (3 – 4 months) render the process economically attractive. (see Figure 1).

Figure 1. Gaseous-phase dehydrogenation of *sec*-butyl alcohol (Deutsche Texaco AG process)
a) Reactor; b) Oil circulation heating; c) Condenser; d) Separator; e) Refrigerator; f) Distillation

sec-Butyl alcohol is dehydrogenated in a multi-tube reactor. The reaction heat (51 kJ/mol) is supplied by heat transfer oil. The reaction products leave the reactor as a gas and are split into liquid crude MEK and hydrogen on cooling. The hydrogen is purified by further cooling. The reaction is highly selective. Autocondensation to higher ketones (e.g., 5-methyl-3-heptanone) is much lower in comparison to acetone. In addition, the dehydration to butenes on copper catalysts is for the most part prevented.

During reaction and subsequent treatment, practically no waste disposal problems arise.

Table 3 lists further processes for the production of MEK by gas-phase hydrogenation of *sec*-butyl alcohol.

4.2. Liquid-Phase Oxidation of *n*-Butane

2-Butanone is a byproduct in the liquid-phase oxidation of *n*-butane to acetic acid. Autoxidation of *n*-butane takes place in liquid phase according to a radical mechanism yielding MEK as an intermediate and acetic acid as the end product. The continuous plug flow process developed by Union Carbide allows the partial collection of MEK intermediate [42]. MEK and acetic acid (mass ratio 0.15 – 0.23 : 1.0) are obtained by non-catalyzed liquid-phase oxidation at 180 °C and 5.3 MPa (53 bar) with remixing. Continuous oxidation under plug flow conditions at 150 °C, 6.5 MPa (65 bar), and a residence time of 2.7 min forms MEK and acetic acid at mass ratios of up to 3 : 1 [42]. Celanese uses acetic acid as a solvent and cobalt acetate and sodium acetate as homogeneously dissolved catalysts [43]. It is a batch process performed at 160 – 165 °C and 5.7 MPa (57 bar). MEK and acetic acid are obtained at a mass ratio of 0.4 : 1.0.

4.3. Direct Oxidation of *n*-Butenes (Hoechst-Wacker Process)

In the direct oxidation of *n*-butenes according to the Hoechst-Wacker process, oxygen is transferred in a homogeneous phase onto *n*-butenes using a redox salt pair, $PdCl_2$/2 CuCl [44], [45]. The salt pair is subsequently reoxidized.

$$n\text{-}C_4H_8 + PdCl_2 + H_2O \longrightarrow CH_3COC_2H_5 + Pd + 2\ HCl$$

$$Pd + 2\ CuCl_2 \rightleftharpoons PdCl_2 + 2\ CuCl$$

n-Butenes can be converted into the following reaction products (conversions of up to 95 % are attained):

Reaction products:	Selectivities, mol %
MEK	86
n-Butyraldehyde	4
Chlorinated products	6
Carbon dioxide	1

The main disadvantages are: formation of chlorinated butanones and *n*-butyraldehyde and corrosion caused by free acids.

Table 3. Further processes for producing methyl ethyl ketone by gase-phase dehydrogenation of *sec*-butyl alcohol

[c] Total yield.

The Maruzen process is similar [46], [47]. Oxygen is transferred by an aqueous solution of palladium sulfate and ferric sulfate.

Other processes employing the same oxygen transfer principle were developed by Consortium für Elektrochemie [48] and Eastman Kodak [49]. For further processes, see [50–53].

5. Quality, Storage, Transportation

It is possible to produce high-purity MEK (DIN 53247, ASTM D 740, BS 1940).

The present sales specifications of Deutsche Texaco AG are listed in Table 4.

Table 4. Sales specifications for MEK

Purity, wt %	GC	min. 99.7
d_4^{20}	(DIN 51757)	0.804 – 0.806
d_{20}^{20}		0.805 – 0.807
Boiling range, °C	DIN 51751	within 0.5
	ASTM D 1078	incl. 79.6
Acidity (as acetic acid), mg KOH/g		0.0001
Water content, wt %,	DIN 51777	
	ASTM D 1364	max. 0.1
Color (Pt – Co, APHA),	ASTM D 1209	max. 10
Nonvolatile matter, wt %		max. 0.002

A stable dilute potassium permanganate solution indicates high purity (permanganate time according to ASTM D 1363).

Storage life of MEK is limited. Carbon steel containers (ST 3529) are suitable for short-term storage and transportation. Stainless steel (316 SS) or containers with a tin lining are recommended for long-term storage. Once autocatalysis has started, it continues even if storage is continued in inert containers. During long-term storage the formation of peroxide must be prevented. Since MEK is somewhat hygroscopic, water is absorbed from the air.

The following regulations for transportation of MEK must be observed [54].

IMDG-Code: D 3308, Kl. 3.2 UN no. 1193, RID, ADR, ADNR: class 3, Rn 301, 2301, and 6301 respectively, no. 1 a, category Kl n; European Council, Yellow Book 78/79: no. 606-002-00-3; European Communities: Guideline/D VgAst, no. 606-002-00-3; UK: Blue Book, Fla.L. IMDG-Code E 3080; USA: CFR 49, 172.101, Fla.L.; IATA RAR: art. no. 726 Fla.L.

6. Uses

MEK is an important solvent with properties similar to those of acetone. MEK has the following advantages in comparison to other solvents with comparable rates of evaporation: very high power of dissolution, high ratio of dissolved matter to viscosity, miscibility with a large number of hydrocarbons without impairing the solids content or viscosity, favorable volume/mass ratio due to its low density.

The following natural substances, plastics, and resins can be dissolved in MEK: rosin, ester resins, pentaerythritol ester resins, Congo ester, dammar (dewaxed), nitrocellulose, low-molecular cellulose acetate, cellulose acetobutyrate, cellulose acetostearate, methylcellulose, epoxy resins, nearly all alkyd and phenolic resins, polyvinylacetate, vinylchloride/acetate mixed polymerizates, vinylchloride/vinylidene chloride mixed polymerizates, coumarone – indene resins, sulfonamide resins, cyclohexanone resins, acrylic resins, polystyrene, chlorinated rubber, polyurethane.

Cellulose triacetate, high-molecular cellulose acetate, poly(vinylchloride), poly(vinylbutyral), polysulfide rubber cannot be dissolved in MEK. Shellac is only partially soluble.

Other areas of application are production of synthetic leather, transparent paper, printing inks, aluminum foil lacquers; degreasing of metal surfaces; extraction of fats, oils, waxes, natural resins; dewaxing of mineral oils [55].

In contrast to its uses as a solvent, use as a chemical feedstock is of minor importance despite the great number of possible reaction; however, condensation with formaldehyde to obtain methyl isopropenyl ketone, autocondensation to form ethyl amyl ketone, and mixed condensation with acetone to obtain methyl amyl ketone are of interest. Methyl ethyl ketoxime, used as an antiskinning agent in lacquers, is of minor importance. Methyl ethyl ketone peroxide is used as a polymerization initiator for unsaturated polyesters. Diacetyl serves as a butter flavorer. The perfume industry reacts MEK with citral to obtain perfume components such as methylpseudoionone. Since 1962 MEK is permitted as an alcohol denaturant in the Federal Republic of Germany (by decree of *Bundesmonopolverwaltung* in Offenbach).

7. Economic Aspects

Table 5 shows the 1979 sales (in %) for the various markets in the Federal Republic of Germany.

The worldwide consumption of MEK in 1979 amounted to 642000 t (Western Europe 166000 t, Eastern Europe 18000 t, North America 315000 t, Central and South America 34000 t, Asia, Australia, Oceania 100000 t, Africa 9000 t).

Table 5. Sales survey (FRG, 1979)

	%
Paints, lacquers, printing inks, aluminum foil lacquers	40
Coating and printing of plastics	20
Chemical industry (incl. sound carrier), pharmaceutical industry	13
Adhesives	11
Miscellaneous	16

MEK is also available under the following names:

German: Ethylmethylketon, Acetonersatz, β-Ketobutan, 2-Butanon

English: Butanone, 2-butanone, MEK, methylacetone, meetco

French: Méthyléthylcétone, butane-2-one, ethylméthylcétone, MEC

8. Toxicology

The odor threshold of MEK is 10 ppm; both, MAK and TLV are established at 200 ppm. The inhalation of MEK vapor has narcotic effects. The vapor irritates the eyes and the nasal and pharyngeal mucous membranes [54]. Frequent and prolonged contact with liquid MEK causes skin moisture loss and slight irritation [56]. Sensitive persons may develop dermatoses [57]. Liquid MEK temporarily irritates the eye and corneas [56].

MEK is usually absorbed through the respiratory tract. It may also be absorbed by the skin, but the cutaneous LD_{50} in rabbits is above 8 mL/kg [57]. The MEK metabolism has been studied in guinea pigs. MEK is both reduced to 2-butanol and oxidized to 3-hydroxy-2-butanone. However, unlike 2-hexanone and *n*-hexane, which are further oxidized to form neurotoxic 2,5-hexanedione after oxidation of the ω-1 C atom, the hydroxybutanone is not further oxidized, but converted to 2,3-butanediol [58].

Animal tests have shown that the neurotoxic effect of 2-hexanone may be potentiated by simultaneous administration of MEK [59], [60]. The chronic inhalation of 200 ppm (MAK, TLV) does not seem to be harmful [61].

Even workroom concentrations of 500–700 ppm over an extended period of time do not cause permanent damage.

The LD_{50} (oral, rat) is 2500–3400 mg/kg [62], [63].

Toxic concentrations for water organisms [54]: average lethal concentration for fish: 5600 mg/L. Maximum permissible concentrations for *Pseudomonas putida:* 1150 mg/L, for *Scenedesmus quadricanda:* 4300 mg/L, for *Microcystis aeruginosa:* 120 mg/L. For small crabs (*Daphnia magma*) the LC_0 is 2500 mg/L, the LC_{50} is 8890 mg/L, and the $LC_{100} > 10000$ mg/L.

1. Introduction

Butenes are unsaturated olefinic hydrocarbons, C_4H_8, M_r 56.1080. There are four isomers:

1 1–Butene

2 *cis*–2–Butene

3 *trans*–2–Butene

4 2–Methylpropene, Isobutene

"Butylenes", the older name for "butenes", is still used today; **4** is frequently referred to as "isobutylene". The designation "*n*-butenes" refers to mixtures of **1, 2,** and **3.**

All the butenes, which do not exist as natural products, have been known for more than 100 years, but remained in very limited use and importance. Scarce availability has been for long the reason. However with the growth of cracking processes in crude oil refining and for ethylene production, butenes have been obtained as coproducts in huge quantities. Since then the complicated nature of the raw C_4 streams, containing besides the four butene isomers also the two butane isomers and multiple unsaturated C_4 hydrocarbons, has been the main barrier for specific chemical use of the butenes.

Until the mid 1980s availability of butene mixtures exceeds by far worldwide the production of the single butene isomers and their derivatives. But during the 1980s the sharp price increase of hydrocarbons accelerated the development of economic separation processes, which opened for the butenes access to appropriate upgraded use.

2. Physical Properties

Butenes are colorless, flammable gases at room temperature and atmospheric pressure. They are completely miscible with alcohols, ethers, and hydrocarbons [1]. Butenes are only slightly water soluble and water is only slightly butene soluble [2]. Important physical properties are summarized in Table 1. Other thermodynamic properties and transport regulations are reported in [3–5].

3. Chemical Properties

Butenes behave as typical olefins. The main reactions are acid-catalyzed addition reactions, isomerization, and polymerization. The four isomers, including two isomers with nonterminal double bonds and one branched-chain olefin, show differences in their chemical behavior: while the 2-butenes as the lowest olefins with nonterminal double bonds generally show a minor chemical activity, isobutene, the lowest branched-chain olefin, exhibits higher reactivity, especially in addition and polymerization reactions. This difference in reactivity permits, e.g.,

the separation of the other isomers through selective reaction of isobutene. The differences in activity (isobutene ≫ 1-butene > 2-butenes) are due to different electron densities, polarities, and steric effects.

Hydration. Acid-catalyzed hydration of butenes is one of the commercially most important processes. Both gas- and liquid-phase processes are used. For kinetic and mechanistic studies see references [6], [7] (→ Butanols). Isobutene yields *tert*-butyl alcohol (TBA). Sulfuric acid (45 wt %) is commonly used as a protonating agent [8]. This process has also been carried out in the presence of sulfonated styrene – divinylbenzene ion-exchangers [9]. The latter liquid-phase process has fewer side reactions, such as formation of di- and triisobutene, less equipment corrosion, and fewer environmental problems. Hydration is commercially used for separating isobutene from mixed butenes.

Hydration of isobutene-free *n*-butenes to form *sec*-butyl alcohol (SBA) is catalyzed under more severe conditions usually by sulfuric acid [10] or more recently by acid ion-exchange resins [11].

Etherification. The acid-catalyzed addition of alcohols to butenes yields alkyl butyl ethers (→ Ethers, Aliphatic). Reaction of isobutene with methanol, yielding methyl *tert*-butyl ether

(MTB or MTBE), is of technical importance. Liquid phase and ion exchange resins as catalysts are commonly used [12]. The etherification of *n*-butenes requires more severe conditions and is of no commercial importance.

Halogenation. 1-Butene reacts with halogens at room temperature to give 1,2-dihalogenbutane and reaction with 2-butenes gives 2,3-dihalogenbutane. Allylic substitution occurs at higher temperatures (> 200 °C). This reaction is of no practical importance. Isobutene readily reacts with chlorine at low temperatures forming methallyl chloride $ClCH_2C(CH_3)=CH_2$ [13].

Hydroformylation. Hydroformylation of butenes in the presence of cobalt or rhodium catalysts gives valeric aldehydes and the corresponding amyl alcohols. *n*-Pentanol and 2-methylbutanol are formed from *n*-butenes, while isobutene gives only 3-methylbutanol [14].

Hydrocarboxylation. The catalyzed reaction of butenes with carbon monoxide and water yields carboxylic acids. Particularly isobutene readily forms pivalic acid $(CH_3)_3CCOOH$ in the presence of strong acid (Koch reaction [15]).

Isomerization. With increasing temperatures the following reactions take place:

cis-2-butene $\rightleftharpoons$ *trans*-2-butene (1)

1-butene $\rightleftharpoons$ 2-butenes (2)

n-butenes $\rightleftharpoons$ isobutene (3)

While *cis/trans*-isomerization (Eq. 1) occurs at ambient temperatures in the presence of catalysts, carbon rearrangement (Eq. 3) requires temperatures of about 450 °C. A large number of catalysts, e.g., Lewis acids, Brønsted acids, metal oxides, and zeolites, are effective. A review of catalysts and equilibrium constants as a function of temperature is given in [16].

Polymerization, Oligomerization. The two types of reactions depend on the catalyst system used:

a) Coordination catalysts (Ziegler-Natta)
b) Liquid or solid Brønsted and Lewis acids

For a review see [17].

Only 1-butene yields high-molecular material such as isotactic or atactic poly-1-butene using Ziegler-Natta catalysts. Isotactic polymers [18] and copolymers with ethylene or propene are produced industrially.

Acidic substances induce poly- or oligomerization by forming carbenium ions [19]. Molecular mass is dependent on many reaction variables, especially temperature: increasing temperature generally results in lower molecular masses.

Polymerization of highly pure isobutene to polyisobutene occurs in an inert solvent at temperatures between − 10 and − 100 °C [20]. Copolymerization with 1 – 3 % isoprene under similar conditions yields butyl rubber. Polymerization of isobutene in butene mixtures in the presence of $AlCl_3$ between − 10 and + 80 °C yields polybutenes with a few percent *n*-butene and isobutane as chain terminators. The molecular masses lie between 300 and 2500. About 80 –95 % of the isobutene is usually converted to polymer [21].

Oligomerization of isobutene to dimers and trimers is done by extracting isobutene from mixed butenes using 65 – 70 wt % sulfuric acid and subsequent heating to 100 °C (cold acid process). An alternative process uses acid ion-exchange resins instead of sulfuric acid (Bayer). The resulting isobutene oligomers, mainly 2,2,4-trimethylpentenes, contain isomeric *n*-butene cooligomers, which increase with higher isobutene conversions. A good part of the accompanying 1-butene is isomerized to 2-butenes [22].

n-Butenes are commercially oligomerized by various homogeneous or heterogeneous catalysts. The Dimersol X Process (IFP), which is commercially applied in Japan (Nissan Oil), uses homogeneous Ziegler-Natta catalysts and forms, in addition to higher oligomers mainly 3-methylheptenes [23]. The Hüls/UOP Octol Process is an example of a heterogeneous catalyzed process which oligomerizes *n*-butenes by different mechanisms depending on the catalyst. The dimers are either mainly 3,4-dimethylhexenes or 3-methylheptenes containing considerable amounts of *n*-octenes and 3,4-dimethylhexenes. A commercial plant is on stream in the Federal Republic of Germany (Hüls).

Highly branched oligomers for fuel are produced by cooligomerizing complete butene

streams alone or in the presence of propene to polymer gasoline (Cat Poly; UOP Catalytic Condensation Process) [24]. The process uses phosphoric acid on kieselguhr.

Dehydrogenation. Dehydrogenation of *n*-butenes is important in the USA for the production of 1,3-butadiene. The reaction is carried out discontinuously at 600 – 700 °C over a chromium/alumina catalyst (Catadiene process, Houdry [25]). Catalytic oxidative dehydrogenation processes in the presence of air and steam running continuously at lower temperatures were later developed (Oxo-D process, Petrotex [26]).

Oxidation. Air oxidation of isobutene [27] or *tert*-butyl alcohol [28] over complex mixtures of transition metal oxides gives methacrolein, which is oxidized in a second reactor to methacrylic acid. The selectivities are between 70 – 80 % at 80 % conversion. Two plants in Japan are in operation (Asahi Glass, Mitsubishi Rayon).

Oxidation of isobutene with ammonia and oxygen to produce methacrylonitrile (ammoxidation) is an extension of SOHIO's propene-based acrylonitrile technology.

n-Butenes and mixed butenes can be oxidized over V_2O_5 /P_2O_5-catalysts to maleic anhydride with selectivities of about 50 – 60 mol %. The temperatures are between 350 and 450 °C. Any isobutene present in the feed is rapidly oxidized to CO, CO_2, and water.

Three plants, one in the Federal Republic of Germany (Bayer [29]) and the others in Japan (Mitsubishi Chemical [30], Nichiyu Chemical) are presently on stream.

Catalytic gas-phase oxidation of *n*-butenes in the presence of steam yields acetic acid [31]. Higher yields can be achieved by liquid-phase oxidation of *sec*-butyl acetate, which is formed in a separate reaction of *n*-butenes with acetic acid [32].

Disproportionation (Metathesis). The Phillips Triolefin Process, which was developed for the production of ethylene and *n*-butenes from propylene, can be reversed to react 2-butenes with ethylene to yield propene. The most common catalyst systems are tungsten, molybdenum, or rhenium complexes; for a review see [33].

Prins Reaction. The acid-catalyzed reaction of isobutene with formaldehyde is the most important synthetic route for isoprene production. Several plants using two-step processes (IFP, Bayer, Kuraray) via intermediate 4,4-dimethylmetadioxane formation are operating in the Former States of USSR, Japan, and Romania [34].

Alkylation. Friedel-Crafts alkylation of aromatics, primarily phenol, *p*-cresol, and catechol, with isobutene in the presence of acid catalysts yields *tert*-butylaromatics. The formation of the thermodynamically favored para-substituted products can be minimized by varying the reaction time, amount of catalyst, and temperature [35].

Alkylation for motor fuel involves reacting mixed butenes with excess isobutane in the liquid phase over sulfuric or hydrofluoric acid catalyst [36]. The main product, aside from numerous other isomers, is 2,2,4-trimethylpentane (isooctane).

4. Resources and Raw Materials

Butenes are rarely made purposely. Almost all butenes are mainly byproducts of gasoline and ethylene manufacture. The operation of these processes is governed by the demand for the major products, while the quantity and composition of the butene streams are left to vary.

Petroleum refining is the largest butene source in the world. Most butenes are generated in catalytic crackers, which convert vacuum gas oils into gasoline and medium distillates. Thermal refining processes (visbreaking, thermal cracking, coking) also byproduce butenes, but their volume is inconsequential compared to the quantity from cat crackers.

The butane – butene ("B – B") streams from catalytic cracking may account for 10 to 13 wt % of fresh feed depending on cracking severity and the catalyst. The butene portion may vary somewhat, but generally comprises about 50 % of the total weight. This is illustrated together with a breakdown of the butenes in Table 2.

Table 3. Estimated world primary production of butenes in 1984 (10^3 t)

cis-2-Butene	11	4

Even though steam crackers account worldwide for only a small percentage of the total butene production, the products from these facilities are more important for chemical use than butenes produced in refineries. The yield of pyrolysis C_4 in olefin plants is highly dependent on the type of feedstock. Liquid feedstocks, i.e., naphtha and gas oil, are converted up to 12 wt % to pyrolysis C_4, while light hydrocar-

bon feedstocks, i.e., ethane and propane yield only roughly 2 or 4 wt %, respectively. More severe cracking conditions favor ethylene formation and lower the higher olefin and butene yields [37]. Typical composition of pyrolysis C_4 obtained by naphtha steam cracking under medium severity is shown in Table 2.

Catalytic dehydrogenation of *n*-butane is only of some importance in Eastern Europe as a source in *n*-butenes, which usually serve as intermediates in the butadiene production. Formerly, *n*-butenes obtained by dehydrogenation were also a major source of butadienes in the USA, but were replaced by the increased amounts of butadiene from steam cracking.

Increasing availability of butanes as condensate from natural gas or gas from crude-oil production (field butanes) in countries far from the consumers has generated plans for new dehydrogenation plants primarily for the production and conversion of isobutene to methyl *tert*-butyl ether (MTB) [38]. Three developed catalytic processes – Houdry's Catofin [39], UOP's Oleflex [40], and Phillip's STAR [41] – are offered for commercial use.

tert-Butyl alcohol (TBA), made by Arco (formerly Oxirane) as a coproduct in its propene oxide plants in the USA and the Netherlands [42], is another source of isobutene.

Ethylene oligomerization processes for production of alpha-olefins with 6 – 20 carbon atoms yield about 10 wt % 1-butene as a byproduct which can be isolated in high purity. Three plants in the USA (Ethyl Corp., Gulf, Shell) and one in Japan (Mitsubishi Chemical) produce 1-butene via this route. The Alphabutol process of IFP for selective dimerization of ethylene to 1-butene is offered for commercial use [43].

Worldwide butene availability, especially as crude mixtures, is enormous. Estimated world primary production of butenes (1984) is given in Table 3. A breakdown into particular areas and sources shows remarkable differences. More than half of the total is generated in North America, but the production of the more valuable butenes from steam cracking is highest in Western Europe.

5. Upgrading of Butenes

Upgrading production of pure butene isomers, their derivatives, or a concentrate of the *n*-butenes, with the above mentioned exceptions, always requires separation from the C_4 mixtures. The pyrolysis C_4 mixture from steam cracking after removal of butadiene, which is recovered in almost all cases by extractive distillation, forms a butene-rich stream known as raffinate-I (Table 4). This is the preferred petrochemical feedstock. Where demand exceeds supply, the more diluted "B – B streams" from cat crackers are also processed.

Table 4. Typical composition (in wt %) of the C_4 fraction from naphtha steam cracking after (1) butadiene extraction (raffinate-I), (2) conversion of isobutene to MTB ∗ (raffinate-II), (3) isobutane removal and selective hydrogenation ∗ (*n*-butene concentrate)

Component	Raff.-I	Raff.-II	*n*-Butene conc.
Isobutane	3	6	< 0.05

1-Butene	25	45	48
1,3-Butadiene	< 0.5	< 0.8	< 0.001
n-Butane	11	19	20
trans-2-Butene	9	17	18
cis-2-Butene	7	13	14

∗ Related to the Hüls process (Fig. 1)

Butenes cannot be separated by mere distillation. Their boiling points are too close together, especially those of isobutene and 1-butene, being the isomers which have established substantial outlets for high purity qualities. Extractive distillation is sometimes used to separate butenes from butanes, but cannot separate butene isomers. Molecular sieve adsorption processes offer potential for isolation of pure butenes [44], but are not yet in commercial use.

Isobutene Separation. All industrially used butene separation processes are based on the higher chemical reactivity of isobutene, the key substance in the butene mixtures. The isobutene derivatives are easily separated and can be split back during a subsequent step to produce pure isobutene or be recovered for particular use. In early stages several similar processes for isobutene separation by reactive extraction with sulfuric acid (45 to 70 wt %) were applied [45]. Isobutene can be isolated in more than 99 wt % purity as *tert*-butanol (TBA) or dimer/trimer

mixture depending on the acid concentration and type of acid regeneration. Only the latter is formed by the so-called "cold acid process", in which higher acid concentrations are added. This process is still widely used to reduce isobutene to < 0.2 wt % in the spent C_4 mixture.

The difficulty and high cost of the traditional processes to separate isobutene has been the main factor in retarding growth of butenes for specific chemical use. Within the 1980s new processes have been introduced that are superior form the view points of economics, environment and energy conservation.

The etherification of isobutene with methanol in the C_4 mixtures to form methyl *tert*-butyl ether (MTB) is the key step in these processes. This very selective reaction takes place in the liquid phase between 40 and 100 °C using a macroporous cation exchange resin as a catalyst. Hüls was the first to modify its raffinate-I based MTB production in 1978 to achieve more than 99.9 % isobutene conversion [46]. All other C_4 components in the co-produced raffinate-II remain unchanged (Table 4). The broad acceptance of MTB as a valuable octane booster opened an unlimited outlet for all surplus isobutene. This, together with the ease of complete isobutene conversion to MTB, makes the corresponding *n*-butenes available, especially as raffinate-II at low cost for specific use. Even though several processes for splitting MTB by reversing synthesis to high-purity isobutene are available [47], none are in commercial use.

Table 5. Isobutene and 1-butene composition (in wt%) in high-purity commercial products (Hüls)

Component	Isobutene	1-Butene
Isobutene	99.98	0.15
1-Butene	0.005	99.70
2-Butenes	0.01	< 0.01
Butanes	0.005	0.15
1,3-Butadiene	< 0.001	< 0.001
tert-Butanol	< 0.0005	< 0.0001
Water	< 0.003	< 0.001
Sulfur	< 0.0001	< 0.0001

Another new process introduced by Hüls in 1981 selectively hydrates isobutene to *tert*-butanol (TBA) under non-corrosive liquid-phase conditions. A cation exchanger acts as catalyst under conditions similar to the MTB process. Equilibrium and incomplete phase miscibility limits the conversion to TBA to about 90 %. Due to the different equilibriums, decomposition of TBA is more favored than that of MTB. The Hüls process decomposes in a second step well below 150 °C heterogeneously catalyzed in liquid phase TBA to high-purity isobutene (Table 5) [9], [48].

***n*-Butene Concentration.** Once isobutene content has been reduced to the raffinate-II level shown in Table 4, recovery of high-purity 1-butene, which is worldwide in growing demand, is possible by fractionation. However, a preceding hydrotreating step is necessary to convert selectively butadiene and traces of acetylenes to achieve the desired product quality (Table 5) [49].

2-Butene is the preferred feedstock for butadiene production by dehydrogenation and is therefore sometimes concentrated. It is of no commercial importance as a high-purity product. Because 1-butene reacts in most cases to the same products as obtained from 2-butene (hydration, esterification, oxidation, oligomerization) the use of 2-butene in mixed *n*-butene concentrates has proved to be a convenient feed for chemical production.

An example of *n*-butene concentrate composition is illustrated in Table 4. Higher concentration can be obtained by removing butanes through extractive distillation or the more recently commercialized molecular sieve adsorption method [50]. Lower concentrations, especially *n*-butane mixtures in the bottom of 1-butene fractionation, are also useful for producing *n*-butene derivatives.

Complementing Process Integration. Whether a butene upgrading process is economical or not depends largely on suitable process combinations. A rather simple combination is e.g. the production of MTB in front of an alkylation of FCC C_4's, whereby the contained isobutene is higher upgraded and alkylation of the remaining butenes becomes independant of the availability of additional isobutane. A steady outlet of the products to the gasoline pool is in such cases generally no problem. More sophisticated systems are required to properly upgrade the more highly valued raffinate-I butenes. Continuous processing of the entire C_4 stream requires that varying demand for different isomers or derivatives be compensated by

Figure 1. Hüls integrated raffinate-I processing

flexible production schedules that allow production of alternate products. This leads to highly integrated process systems. Figure 1 shows the Hüls scheme for raffinate-I processing.

Raffinate-I is fed in a variable ratio to the synthesis of TBA and MTB. Primary product of the TBA synthesis is a TBA/water mixture that is either decomposed to give high-purity isobutene or purified to give TBA/water azeotrope and dehydrated TBA. The raffinate-I not required for TBA/isobutene is conjointly used with remaining C_4 compounds from TBA synthesis in MTB production. Whereas TBA is more easily converted to pure isobutene, MTB is the more economic gasoline improver and according to its thermodynamically favored synthesis isobutene conversion is accomplished for the total stream, resulting in virtually isobutene-free raffinate-II (Table 4).

Isobutane is separated together with water from the raffinate-II by fractionation. Selective hydrogenation of the bottom product leads to *n*-butene concentrate with a composition shown in Table 4. Fractionation of the *n*-butene concentrate yields polymerization grade 1-butene. The 2-butene/*n*-butane mixture remaining after 1-butene separation is like any surplus of *n*-butene concentrate suitable for the production of di-*n*-butenes through oligomerization.

6. Quality Specifications

Due to different production processes and applications, no standard quality specifications for the butenes are available. The two isomers which have become commodities as high purity products show in general a purity greater than 99 wt %. Table 5 illustrates the typical isobutene and 1-butene composition as obtained through the Hüls processes.

7. Analysis

Analysis of pure butenes and butene mixtures containing *n*-butane, isobutane, 1,3-butadiene, small amounts of C_3- and C_4 acetylenes, and diolefins are generally performed by gas – liquid chromatography. A routine GLC-analysis using a packed column is described in the ASTM Method D-1717.

An Al_2O_3 capillary column (Chrompack) permits the simultaneous determination of all C_1- to C_5-components combined with improved detection (usually $\leqq 5$ ppm).

The water content of butenes often plays an important role in further processing. It can be determined either by Karl Fischer titration [51] or more precisely by a commercial on-line hygrometer (e.g., Panametrics).

All other impurities are determined by general standard methods.

8. Storage and Transportation

Butenes are usually stored and transported as pressurized liquids.

Most countries have specific legislation pertaining to the erection and operation of tank farms for LPG as butenes.

The following regulations pertaining to the transport of dangerous goods must be observed while transporting butenes:

GGVE/GGVS:

class 2, number 3 b

RID/ADR:

class 2, number 3 b

ADNR:

class 2, number 6, category F

IMDG-Code/GGVSee:

class 2, UN-No. 1012 (*n*-butenes)
class 2, UN-No. 1055 (isobutene)

IATA-DGR/ICAO-Code:

class 2 (3) UN-No. 1012 (*n*-butenes)
class 2 (3) UN-No. 1055 (isobutene)

The transport containers for butenes (steel cylinders, steel drums, road tankers, pressure gas tank wagons and tank containers) must conform to these regulations in respect to construction materials, design, fittings, and marking. They must be approved for use at not less than 1 MPa (10 bar) test pressure.

9. Uses and Economic Data

The estimated world butene consumptions in 1984 are shown according to regions in Table 6. More than half of the butenes produced worldwide are utilized as alkylate and polymer gasoline. One third is used without any conversion as fuel, mainly as fuel gas or blendstock for gasoline. Only about 15 % of the butenes are converted to specific chemicals. Even the greater part of the isobutene transformed to pure MTB is ultimately burned as a gasoline component.

Table 6 shows some remarkable regional differences. In North America, Western Europe, Eastern Europe, and Japan, most butenes are converted into higher value gasoline components and chemical products, whereas in industrially less developed regions, butenes are usually directly used without further conversion for their calorific value.

Alkylate Gasoline. In North America nearly 80 % of butenes are converted into alkylate gasoline, whereas alkylate gasoline plays a lesser role in other regions. However, since more than half of all butenes are produced in North America, almost 50 % of the butenes used worldwide are converted into alkylate gasoline, the largest outlet for butenes.

Polymer Gasoline. The oligomerization of butenes, in most cases mixed with propene, gives highly branched C_6-C_{12} -olefins [24]. It is the oldest method for reconverting the low boilers obtained from catalytic cracking into higher molecular mass gasoline components. This was an important process, particularly in the 1940s, for the production of aviation fuel. Today, it has been largely replaced by alkylation, which gives higher octane rating products.

Straight Fuel. Butenes are also used directly for such diverse applications as a blendstock in gasoline, LPG, and as plant fuel. The least demand exists in North America, where paraffinic light hydrocarbons are readily available from natural gas liquids and butenes are more highly valued as alkylation feedstock. Consumption is higher in areas as Europe, where LPG production is more or less restricted to refineries.

Methyl tert-Butyl Ether (MTB). MTB is almost exclusively admixed to carburetor fuels as an octane booster. It showed the highest growth rate of all butene derivatives during the last decade [52]. Since the isobutene in raffinate-I is already largely utilized, isobutene from catalytic cracking or other sources – upstream of alkylation – is increasingly used as feedstock for the production of MTB [53].

tert-Butanol (TBA). Large quantities of TBA from isobutane are obtained as a byproduct of propene oxide production by ARCO [42]. It is predominantly used in its impure form as blending component for gasoline [54] or to produce pure isobutene (see Table 3).

Smaller quantities of pure TBA are obtained by direct hydration of isobutene-containing C_4 cuts. This process, only is in use in Japan and the Federal Republic of Germany, serves also for the isolation of pure isobutene via TBA. That portion is not included in the figures in Table 6. This pure TBA is in Japan predominantly used for the production of methyl methacrylate [28]. Other countries use TBA as a solvent for the production of *tert*-butyl peroxides or as a stabilizer for chlorinated hydrocarbons among others.

Di- and Triisobutenes. The decreased use of sulfuric acid extraction for isobutene separation has resulted in di- and triisobutene production for chemical use only.

Diisobutene is mainly used for the production of isononanol and octylphenol, which are required as intermediates for plasticizers and detergents, respectively.

Butyl Rubber. More than half of the 1 million tons of high-purity isobutene produced in 1984 was converted to butyl rubber. Butyl rubber, which is made by copolymerizing high-purity isobutene with small amounts of isoprene, is used mainly as a tire inner liner because of its excellent air impermeability.

Also included are the smaller amounts of so-called polyisobutene, which does not contain any comonomers and is used in films, among others [20].

Polybutene. Polybutene is a polymerization product of isobutene obtained directly from raffinate-I or the catalytic cracker C_4 cut and contains therefore about 2 % *n*-butene. The largest portion is in the 1000 molecular mass range and is used as a precursor for lube oil additives [55]. Polymers with higher molecular masses are used as caulks and sealants.

Isoprene. Isoprene can be directly extracted from the steam cracker C_5 cut or synthesized by reacting formaldehyde with pure isobutene. Even though this process is only used in Eastern Europe, especially in the Former States of USSR, and in one plant in Japan, isoprene production via isobutene is the second largest outlet of pure isobutene.

Butadiene. Although butadiene production via *n*-butene dehydrogenation is the single largest *n*-butene consumer for chemical use, less than 15 % of worldwide butadiene production in 1984 was based on dehydrogenation of *n*-butenes. Even in the United States, where dehy-

drogenation was once dominating, it is presently only used to augment the supply when butadiene from extractive distillation of steam cracker C_4 cut is in short supply. Butadiene production by two-step dehydrogenation via *n*-butane is used in countries with an ample butane supply, such as the Former States of USSR and Mexico.

1-Butene in Polyolefins. High-purity 1-butene demands have multiplied during the 1980s and are expected to continue to grow at this rate [56]. Most is used as a comonomer for linear low-density polyethylene (LLDPE), which contains up to 10 %. However, 1-butene is also used as a comonomer for modifying high-density polyethylene (HDPE), which contains up to 4 %.

Shell in the United States uses about 20000 t of high-purity 1-butene for the production of poly-1-butene per year.

sec-Butanol (SBA). SBA made by hydration is after butadiene quantitatively the second most important product from *n*-butenes. Raffinate-II is a typical feed material. Almost all the SBA is further converted by catalytic dehydrogenation into methyl ethyl ketone (MEK), which is mainly used as a solvent and diluent in the surface-coating and plastic industries.

Special Chemicals. Butenes are used to produce various special chemicals.

Isobutene derivatives include, among others, phenols, such as 4-*tert*-butylphenol, 2,6-di-*tert*-butyl-4-methylphenol (BHT), 2- or 3-*tert*-butyl- 4-hydroxyanisole (BHA), most of which are used as stabilizers. Other isobutene derivatives worth mentioning are *tert*-butylamine (intermediate for lubricating oil additives), *tert*-butylmercaptan (gas odorant), pivalic acid, 3-methylbutyric acid (isovaleric acid), 3-methyl-1-butanol, methallyl chloride, and triisobutylaluminum.

With a few exceptions, such as *n*-butene 1,2-oxide (stabilizer for chlorinated hydrocarbons) *n*-butene derivatives are generally derived from mixtures (raffinate II or *n*-butene concentrate). These include oligomers (intermediates for plasticizers, detergents, and lube oil additives), maleic anhydride, the oxo derivatives *n*-valeric acid, and 2-methylbutyric acid, and the corresponding alcohols 1-pentanol and 2-methyl-1-butanol, which are primarily used as solvents.

10. Toxicology

A specific toxic action of the butenes is not known. They have, however, a narcotic action at higher concentrations causing vomiting, giddiness, and intoxication. Butene gas in high concentrations, as built up by rapid evaporation, displaces atmospheric oxygen so that there is a danger of suffocation. The symptoms, however, disappear rapidly in fresh air.

Skin contact with the liquid causes frost bite due to the high negative heat of vaporization. Toxicological data are available only for isobutene.

Acute toxicity of isobutene:

LC_{50}, inhalation, rats: 620 g/m^3 4 h
LC_{50}, inhalation, mice: 415 g/m^3 2 h [57]

Chronic toxicity of isobutene:
Isobutene shows little chronic toxicity because rats inhaling high doses (up to 8000 ppm) for 90 days show no evidence of any toxicological effects. Evidence of mutagenic or cell transforming activity (Ames Test, Mouse Lymphoma Assay, Cell Transformation Study) is also absent [58].

1. Introduction

γ-Butyrolactone or γ-hydroxybutyric acid lactone [*96-48-0*], $C_4H_6O_2$, M_r 86.09, became industrially available in the 1940s as a result of the work of W. Reppe and his colleagues at BASF.

To date, the Reppe process (see Chap. 4) has remained the most important process for the production of butyrolactone. Butyrolactone is important as an intermediate in the manufacture of pyrrolidone derivatives and as a solvent for polymers and agrochemicals.

Methods of synthesis of historical and preparative interest are summarized in *Beilstein* [1] and in *Houben-Weyl* [2]. In the mid-1960s butyrolactone was discovered in nature, as a normal metabolic product in animals [3].

2. Physical Properties

Butyrolactone, *mp* −43.5 °C, *bp* 204 – 206 °C (at 101.3 kPa), is a colorless, slightly hygroscopic liquid having a faint odor. Butyrolactone is miscible in all proportions with water, alcohols, esters, ethers, ketones, and aromatic hydrocarbons. It has limited miscibility with linear and cyclic aliphatic hydrocarbons. It is an excellent solvent for numerous polymers and a selective solvent for lower hydrocarbons. Some physical properties of γ-butyrolactone are listed below.

Density	
at 0 °C	1.15 g/cm^3
at 20 °C	1.13 g/cm^3
at 40 °C	1.11 g/cm^3
Critical temperature $T_{\mathrm{crit.}}$	436.5 °C
Critical pressure $p_{\mathrm{crit.}}$	3.35 MPa
Vapor pressure	
at 20 °C	0.04 kPa
at 50 °C	0.3 kPa
at 100 °C	3.6 kPa
at 150 °C	22.5 kPa
at 205 °C	101.3 kPa
Heat of vaporization at 206 °C	535 kJ/kg
Heat of solution in water	2500 J/mol
Specific heat capacity c_p (l)	
at 25 °C	1680 J kg^{-1} K^{-1}
at 100 °C	1850 J kg^{-1} K^{-1}
at 200 °C	2200 J kg^{-1} K^{-1}
Specific heat capacity c_p (g)	
at 100 °C	1275 J kg^{-1} K^{-1}
at 200 °C	1575 J kg^{-1} K^{-1}
at 300 °C	1820 J kg^{-1} K^{-1}
Evaporation number (DIN 53170)	216
Flash point (DIN 51758)	100 – 101 °C
Ignition temperature (DIN 51794)	455 °C
Heat of combustion at constant volume or constant pressure	234 kJ/g
Explosion limits	
lower	2.7 vol %
upper	15.6 vol %
Refractive index n_D^{20}	1.4352
Viscosity	
at 20 °C	1.90 mPa · s
at 50 °C	1.25 mPa · s
at 80 °C	0.86 mPa · s
at 110 °C	0.63 mPa · s
at 140 °C	0.49 mPa · s
at 170 °C	0.40 mPa · s

Thermal conductivity (25 – 65 °C)	0.276 J m^{-1} s^{-1} K^{-1}
Conductivity	0.7 µS/cm

3. Chemical Properties

In aqueous solution there is an equilibrium between the lactone and free hydroxybutyric acid, which lies 100 % on the lactone side at 0 °C, and about 80 % at 100 °C. In the presence of one molar equivalent of alkali, the equilibrium is displaced 100 % to the hydroxybutyric acid side; therefore, butyrolactone can be determined by titration with a base. At pH 7 the compound is extremely stable. Butyrolactone reacts with bases, hydrogen halides, and alcohols (in the presence of acids), undergoing ring cleavage and giving derivatives of γ-hydroxybutyric acid. It reacts with ammonia, amines, carbonyl compounds, and halogens in the α-position without ring cleavage. For example, butyrolactone condenses with ethyl acetate [*141-78-6*] to give α-acetobutyrolactone, an intermediate in the production of vitamin B_1:

Cleavage of the lactone ring gives derivatives of γ-substituted butyric acid. For example, butyrolactone reacts with sodium sulfide to give the rubber additive thiodibutyric acid [*5152-99-8*]:

Reaction with phenols gives phenoxybutyric acids [*6303-58-8*]:

Replacement of the ring oxygen atom by nitrogen yields pyrrolidone derivatives, a reaction often used in industry. For example, butyrolactone reacts with methylamine [*74-89-5*] to give *N*-methylpyrrolidone [*872-50-4*]:

The chemistry of butyrolactone, and its use in a variety of syntheses, was investigated, above all, by W. Reppe [4] and others [5]. Reactions, generally typical of lactones, are described in *Houben-Weyl* [2].

Homopolymerization of butyrolactone can be effected only under very high pressure (2000 MPa) [6].

4. Production

Dehydrogenation of 1,4-Butanediol [*110-63-4*] (→ Butanediols, Butenediol, and Butynediol). The Reppe process for manufacturing butyrolactone involves theendothermic dehydrogenation of 1,4-butanediol in the gas phase. This process is used by BASF, ISP, and Lyondell.

$\Delta H = +61.6$ kJ/mol

Preheated 1,4-butanediol vapor is introduced into a hot stream of circulating hydrogen and passed at atmospheric pressure through a bed of copper catalyst at temperatures between 180 and 240 °C (Figure 1). The yield of butyrolactone is approximately 95 %. The reaction takes place via γ-hydroxybutyraldehyde [*25714-71-0*] [7].

The byproduct hydrogen off-gas requires only simple purification before reuse (e.g., catalytic methanization of carbon monoxide impurities). The crude butyrolactone separated from the recycle gas stream contains small amounts of byproducts, including 1,4-butanediol, butyric acid, and high boilers, from which butyrolactone is separated by distillation.

Butyrolactone itself is noncorrosive and can be handled in carbon steel apparatus. However, where parts of the synthesis or distillation vessels and pipes come into contact with hot crude product containing butyric acid, they must be made of stainless steel.

Figure 1. Production of γ-butyrolactone by dehydrogenation of 1,4-butanediol

Hydrogenation of Maleic Anhydride [*108-31-6*]. In the preparation of butyrolactone by hydrogenatingmaleic anhydride, molten maleic anhydride is fed into a preheated circulatingstream of hydrogen and passed under a pressure of 6 – 12 MPa at 160 – 280 °C over a nickel-containing catalyst [8].

$\Delta H = -211$ kJ/mol

The reaction takes place via succinic anhydride [*108-30-5*] and can, by choice of the conditions, be continued to produce tetrahydrofuran [*109-99-9*]. The excess hydrogen is washed with water and recycled tothe synthesis. Byproducts contained in the butyrolactone are separated out of the circulating gas: propanol [*71-23-8*], butanol [*71-36-3*], propionic acid [*79-09-4*], and butyric acid [*107-92-6*]. The butyrolactone is separated from these by distillation.

Because of the acids present, both the synthesis apparatus and the distillation apparatus must be made of stainless steel. The Japanese manufacturer Mitsubishi Chemical Corporation [9] uses this process.

Hydrogenation of Maleic Esters. New processes for the production of 1,4-butanediol and tetrahydrofuran starting from maleic anhydride via dimethyl maleate have been developed in the past few years (→ Tetrahydofuran). They offer the possibility of extracting butyrolactone, which is an intermediate in these processes.

In a process developed by Kvaerner Process Technology (KPT, London) [10] dimethyl maleate [*624-48-6*] is producedin a first step from maleic anhydride and methanol with a strongly acidicion exchanger as catalyst. The resulting dimethyl maleate is hydrogenated in the gas phase on a Cu-containing catalyst at a pressure of 2 – 8 MPa at 150 – 250 °C and gives a mixture of 1,4-butanediol, tetrahydrofuran, butyrolactone, and a small amount of the intermediate dimethyl succinate [*106-65-0*].

Butyrolactone and dimethyl succinate can be recovered as an azeotrope and recycled to the hydrogenation stage to obtain complete conversion to 1,4-butanediol and tetrahydrofuran. Alternatively the azeotrope can be refined by distillation to recover pure butyrolactone. The amount of butyrolactone depends on the pressure and temperature in the hydrogenation step, which influence the equilibrium between 1,4-

butanediol and butyrolactone. Under the conditions described above it may vary from 5 to 50 %.

The new process has been licensed by KPT several times. The first commercial plants using this process are expected to come on stream in 2000.

A proprietary process practised by Eurodiol, a Belgian company of the SISAS group also starts from dimethyl maleate, which is hydrogenated in the gas phase at 1 – 2 MPa to give a mixture of butyrolactone and tetrahydrofuran in variable proportions. Butyrolactone and tetrahydrofuran are recovered as pure products by distillation, while the byproduct azeotrope butyrolactone/dimethyl succinate can be recycled for full conversion to butyrolactone and tetrahydrofuran or hydrogenated in a subsequent hydrogenation step in the liquid phase to give 1,4-butanediol and additional tetrahydrofuran.

Other Processes. Processes via tetrahydrofuran [11], dihydrofuran [12], acetylene [13], [14], butynediol [15], olefins [16–18], butadiene [8], or by carbonylation [19–21] are not industrially important.

Producers. Butyrolactone is manufactured by BASF (Ludwigshafen, Germany and Geismar, USA), ISP (Calvert City and Texas City, USA), Lyondell (Channelview, USA), MCC (Mizushima, Japan) and Eurodiol (Feluy, Belgium).

5. Quality Specifications and Analysis

Standard-grade butyrolactone is about 99.7 % pure. The main impurities in the Reppe-based process are 1,4-butanediol, butyric acid, and water; in the maleic ester based processes, dimethyl succinate, 4-hydroxybutyl butyl ether, and water. Electronic-grade butyrolactone is about 99.9 % pure and is subject to stringent restrictions regarding the content of specific ions such as Fe ions, Na^+, Cl^-, NO_3^-.

Butyrolactone is usually analyzed by gas chromatography. The butyric acid content can be determined by titration with alkali. The water content is determined by coulometric titration. Cations and anions are analyzed by atomic spectroscopy and ion chromatography, respectively.

6. Storage and Transportation

Butyrolactone can be stored indefinitely. The pure product is noncorrosive and therefore can be stored and transported in carbon steel containers. Butyrolactone becomes slightly yellow on prolonged storage in carbon steel vessels without nitrogen padding. In this case stainless steel containers are recommended. The hygroscopicity of the product requires some precautions. Butyrolactone attacks concrete vigorously.

For detailed transport information (classification, regulatory data etc.), see the safety data sheet [22].

7. Uses

The main use of butyrolactone is as an intermediate in the synthesis of *N*-methylpyrrolidone (NMP) [23], pyrrolidone [24], herbicides (e.g., MCPB = γ-2-methyl-4-chlorophenoxybutyric acid) [25], growth regulators (e.g., α-(4-methylbenzylidene)-γ-butyrolactone [*5418-24-6*] [26]), α-acetobutyrolactone (a vitamin B_1 intermediate) [27], and the rubber additive thiodibutyric acid [28]. Butyrolactone is used as a solvent for polymers [29], [30] and as a polymerization catalyst [31]; in hairwave compositions [32] and sun lotions [33]; and in pharmaceuticals [34]. It is also used in printing inks, e.g., for ink-jet printing [35], as an extractant in the petroleum industry [36], as a stabilizer for chlorohydrocarbons [37] and phosphorus-based pesticides [38], and as a nematocide [39]. More recent applications are in the electronics field as a cosolvent for capacitor electrolytes [40] and as a cosolvent for photoresists [41].

8. Toxicology and Occupational Health

γ-Butyrolactone is readily absorbed from the intestine and through the skin [42], [43]; the half-life was about 20 min in the blood of rats after oral administration [43]. Metabolism and excretion is rapid; γ-hydroxybutyric acid is the primary metabolite. Following i.v. injection in rats, ca. 60 % of radiolabeled lactone was detected in the expired air as CO_2

within 2.5 h with the peak level about 20 min after application [44]. In human volunteers who received 1 g of γ-butyrolactone in water, (*S*)-3,4-dihydroxybutyrate, glycolic acid, γ-hydroxybutyrate, and an isomer of 4-hydroxy-3-oxobutyrate were analyzed in the urine 4 h after application [45].

γ-Butyrolactone has a low acute toxicity: LD_{50} data in the literature vary between 800 and 1800 mg/kg (rat, mouse) and 500 and 1700 mg/kg (guinea pig). The dermal LD_{50} in guinea pigs is 5600 mg/kg [46], [47], [48]. The inhalative LC_{50} (rat, 4-h) lies above the highest tested concentration which did not cause mortality (>5.1 mg/L) [49]. Inhalation (8-h) of air saturated with γ-butyrolactone at room temperature produced no symptoms in rats [50].

γ-Butyrolactone causes depression of the CNS by means of its metabolite γ-hydroxybutyric acid and, in addition, anesthetic effects on the peripheral nervous system [51], [52].

In adult human volunteers, a dose of 2500 mg per person (estimated dose: 35 – 45 mg/kg) induced a 1-h sleep [53]. When used as an anesthetic in children, 66 mg/kg of γ-butyrolactone resulted in deep sleep with rare cases of respiratory depression [54]. Higher specific oral doses, accidentally ingested by adults or infants, are reported to have caused unconsciousness within minutes due to CNS depression, occasionally coma, as well as brachycardia and respiratory depression. The patients had to be provided supportive medical treatment, but apparently recovered completely within ca. 24 h [55], [56].

In rabbits, γ-butyrolactone does not cause primary skin irritation but is irritating to the eye [50]. It does not cause skin sensitization in guinea pigs [57]. In humans, no skin reactions were seen after patch-testing of γ-butyrolactone for skin-contact allergy in 200 volunteers [47]. Lotions containing γ-butyrolactone are well tolerated when applied to the skin [51]. The substance served as successful topical analgesic for the relief of pain arising from local injuries of the musculoskeletal system, including rheumatic complaints, or from headache (e.g., migraine) [51].

Prolonged administration of γ-butyrolactone in drinking water for four weeks at a daily dosage of 3 g/kg led to depression of the CNS in rats. Apart from a slight reduction in body weight gain, the animals showed no further health effects [58]. The low toxicity can be explained by the fast metabolism and elimination. In animal studies with repeated oral administration by gavage to rats and mice, somewhat higher toxicity was observed than with application via drinking water (bolus effect) [59].

The majority of the large number of mutagenicity and genotoxicity studies provides evidence that γ-butyrolactone is devoid of genotoxic potential [47]. Several repeated dose [58], [60] and lifelong carcinogenicity studies [47], [59] failed to reveal any signs of chronic organotoxic effects by any route of application. Two valid two-year (lifetime) carcinogenicity studies in rats and mice receiving up to 450 or 525 mg kg^{-1} d^{-1}) of γ-butyrolactone by gavage (5 d per week in corn oil) showed no evidence of tumorigenic potential. The slight increase of pheochromocytomas in low-dosed male mice was interpreted by the authors as an equivocal response [59]. These findings principally confirmed the consistently negative results found in early dermal and oral studies [61], [62], [47] and therefore allow the conclusion that no significant carcinogenic potential is attributable to γ-butyrolactone.

Prenatal exposure to γ-butyrolactone gave no evidence of substance-related developmental toxic effects either by the oral route (rats, 10 – 500 mg kg^{-1} d^{-1}) [63] or by inhalation (rabbits, 0.5 – 5 mg/L air) [64].

In Europe and the United States, no specific occupational exposure limits for γ-butyrolactone have been established.

Experimental acute toxicity data and its ready degradability suggest that γ-butyrolactone is unlikely to pose any risk to the environment [65], [66].

1. Introduction

Cadmium [*7440-43-9*], Cd, atomic number 48, A_r 112.40, belongs to the zinc subgroup of the periodictable along with mercury. In its compounds it has an oxidation state of +2. There are eight natural isotopes, with mass numbers ranging from 106 – 116. The most abundant are ^{114}Cd (29 %) and ^{112}Cd (24 %). There are also a number of metastable isotopes.

STROHMEYER discovered cadmium in 1817 in the course of investigating zinc carbonate. He recognized that the yellow color of a sample of zinc oxide produced by roasting was due to the presence of an unknown metal oxide. Because this new element also occurred in the zinc ore calamine, a name derived from the Latin word "cadmia," he named the new element cadmium.

Unlike some other heavy metals, such as lead or mercury, which have been used since ancient times, cadmium has been refined and utilized only relatively recently. After its discovery more than a century elapsed before the metal or its compounds were employed to any significant extent. Only since the 1940's production and consumption have risen distinctly. The primary uses are electroplated cadmium coatings, nickel – cadmium storage batteries, pigments, and stabilizers for plastics. Publicity about the toxicity of cadmium has affected the consumption.

2. Cadmium Metal

2.1. Physical Properties

Cadmium is a soft, ductile, silver-white metal. Like tin, it makes a grating sound when bent. The most important physical properties are given below.

mp		320.9 °C
bp		767 ± 2 °C
Vapor pressure at	218 °C	0.133 Pa
	302 °C	6.666 Pa
	392 °C	133.32 Pa
	485 °C	1333.2 Pa
	611 °C	13.332 kPa
	727 °C	66.660 kPa
	765 °C	101.33 kPa

Density	8.64 g/cm^3
Specific heat at 20 °C	0.230 J g^{-1} K^{-1}
Heat of fusion	55 J/g
Heat of vaporization at 767 °C	890 J/g
Thermal conductivity at 18 °C	92 J m^{-1} s^{-1} K^{-1}
Electrical resistivity at 18 °C	7.5 × 10^{-6} Ω cm
Brinell hardness	22 – 24

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a04_499

Coefficient of linear expansion at 20 °C	$31 \times 10^{-6}\ K^{-1}$
Ionization potential	8.96 V
Electrochemical potential	− 0.40 V
Cross section for thermal neutrons	$2450 \times 10^{-28}\ m^2$

The crystal structure is distorted closest packed hexagonal.

2.2. Chemical Properties

Cadmium is stable in air; only a slight loss in luster occurs after an extended period of time in air. When it is heated, initially yellow to brown colors develop as a thin oxide layer forms. If the metal is heated to volatilization, it burns with a red-yellow flame to form brown cadmium oxide, which is poisonous. Cadmium dissolves readily in nitric acid but only slowly in hydrochloric or sulfuric acid and not at all in bases. Zinc displaces it from solution.

2.3. Occurrence, Raw Materials

Cadmium is widely distributed. It occurs in the earth's crust with a content estimated to be between 0.08 and 0.5 ppm. In top soil cadmium content usually lies between 0.1 and 1 ppm.

The best known cadmium mineral is greenockite, cadmium sulfide (77.6 % Cd). One mineral form of cadmium carbonate (61.5 % Cd) was named otavite after its discovery site, the Tsumeb Mine, in the Otavi deposit of South-West Africa. In Sardinia, pure cadmium oxide (87.5 % Cd) was found in a zinc deposit. However, none of these cadmium minerals is of industrial importance because the deposits are too small.

Only zinc minerals in which cadmium is found as an isomorphic component, with concentrations ranging from 0.05 to 0.8 %, averaging about 0.2 %, have economic significance for cadmium recovery [2]. In addition, lead and copper ores contain small amounts of cadmium, which can be separated during the roasting and smelting processes.

2.4. Refining

Figure 1 summarizes the individual process steps and their combination. Detailed description, with emphasis on the distillation process, can be found in [3].

Figure 1. Processes for the production of cadmium metal

2.4.1. The Starting Materials

The flue dust on which the volatile cadmium collects when zinc, copper, and lead ores are heated in air are the primary starting material for cadmium recovery and refining. In many cases it is necessary to recirculate this dust to obtain higher cadmium concentrations [4].

In the Outokumpu Zinc Works in Finland, roasting material contains 0.19 – 0.24 % Cd. The cadmium content is extracted in the third step of the zinc process and results in a cake consisting of 90 % cadmium and 10 % zinc. This is the starting material for further processing [5].

If the primary flue dust is reduced in a rotary oven, lead and zinc remain in the oven, while the cadmium is volatilized and enriched in the secondary flue dust.

In the Berzelius Metal Works, Duisburg, Federal Republic of Germany, complex lead–zinc ores are refined by the Imperial smelting process. When the concentrate is roasted in the sintering furnaces, cadmium-containing flue dust

is produced. This is leached in an acid solution, and the cadmium is subsequently precipitated as cadmium carbonate. The cadmium in secondary raw materials, such as steel mill dust, leaching sediments, and sludge from water treatment, can be processed at the same time. However, before they are mixed with the concentrates they are enriched in a rotating tube furnace (Waelz process).

In hydrometallurgical zinc refining, the cadmium-containing zinc concentrate is leached with sulfuric acid. The cadmium is removed from the solution together with copper by reduction with zinc dust to give a metallic sludge. Similar cadmium sludges form in the purification of zinc solutions used in the production of zinc sulfide pigments or zinc carbonate. These cadmium sludges are the most important starting materials for cadmium refining today. The secondary starting materials mentioned above can be added to the primary raw materials without causing large alterations in the refining process.

Also of economic significance is the recycling of used nickel – cadmium storage batteries; cadmium-containing alloys, such as Sn – Cd metallizing alloys from the manufacture of rectifiers; defective industrial batches; residues from the production of cadmium pigments; and cadmium-containing fluorescent materials. Special processes are usually necessary to convert the cadmium content into a form that can be processed normally. The most important processes of this type are discussed in Section 2.4.6.

2.4.2. Leaching of the Starting Materials and Cementation

Cadmium is extracted from the enriched starting materials by oxidizing solutions. The extraction must be carried out in such a way that all the cadmium as well as the zinc dissolves. The procedure of Ruhr Zinc, Datteln, Federal Republic of Germany, is described here as an example. The liquid from electrolytic baths, which has a sulfuric acid concentration of 25 – 30 g/L, is conveyed into 50 m^3 tanks. In order to oxidize the cadmium, either air is blown in or manganese dioxide is added. Fresh cadmium sludge or cadmium carbonate is added to decrease the acidity of the solution, and a copper-containing precipitate is removed with a filter press. Zinc, cadmium, and thallium are almost completely dissolved in the solution along with almost no copper, cobalt, nickel, and arsenic [6].

Copper chloride mixed with other metal chlorides or iron(III) chloride can be used as an oxidant instead of air [7], [8]. Dust from the sintering process can also be roasted to give sulfates and then be extracted in a similar fashion with water [9].

Independent of the further processing of the cadmium, it is precipitated from the solution as a metal sponge by reduction with zinc. If necessary the solution is purified first.

The cadmium raw solution resulting from the leaching step at Ruhr Zinc contains about 30 g/L of zinc and small amounts of cobalt, nickel, thallium, and copper in addition to the 30 – 40 g/L of cadmium. The cadmium is precipitated in a 50 m^3 tank at a temperature of 60 °C. In order to avoid excess zinc in the cadmium sponge, only 80 % of the stoichiometric amount of the zinc is added initially. The remaining zinc dust is added in small portions until the cadmium concentration of the solution is below 0.1 g/L. After decanting, the cadmium sponge is left in the reaction container. The precipitation is carried out three times, principally to reduce the amount of zinc. After the final precipitation, the sponge is washed, and the wash water is recycled to the zinc plant. The precipitated sponge contains 90 % cadmium and only 2.5 % zinc [6].

The procedure of the Outokumpu Zinc Works starts with a purified cadmium solution because of the nature of the succeeding metal recovery (see Section 2.4.5). Copper is removed with zinc powder, and lead is removed with barium carbonate. The separation of the cadmium sponge from the solution, however, scarcely deviates from the Ruhr Zinc processes. The greatest difference is that the cementation is interrupted at cadmium concentrations of 3 – 5 g/L, and the solution recirculated. Together with a very careful wash, this reduces the residual content of zinc in the compacted cadmium-sponge briquettes to 0.5 – 2.0 % [5].

2.4.3. Electrolytic Recovery

The largest amounts of cadmium are recovered electrolytically. It is customary to extract the cadmium sponge in the same tank with

the cadmium-containing electrolytic acid. Air is supplied at a temperature of 80 °C for 6 – 10 h. Concentrated sulfuric acid is added to keep the concentration of free sulfuric acid at 100 g/L. Manganese dioxide can also be used as oxidant [6].

The time required to dissolve the cadmium sponge at room temperature can be reduced by blowing air through special reactors. The relationship between solid and liquid, the amount of air, and the pH are carefully controlled to reduce the time and temperature required for the dissolution [10].

The electrolytic deposition of cadmium requires that the impurities that cause problems during the electrolysis or that are deposited as impurity with cadmium be removed prior to electrolysis. Traces of copper can be removed by addition of small quantities of sodium sulfide in the form of copper sulfide or by cementation with zinc dust. Thallium is removed as thallium dichromate by addition of potassium dichromate. Thallium can also be removed as thallium(III) hydroxide by addition of potassium permanganate. Any arsenic is eliminated as iron arsenate by oxidation with the potassium permanganate. The lead remaining in solution is removed by adding strontium carbonate to occlude lead carbonate [6].

The anode consists of lead, which does not dissolve, and the cathode is sheet aluminum. Today rotating cathodes, which allowed high current density, have disappeared because current densities of 100 A/m^2, permitting economic electrolysis, can also be attained with fixed cathodes. However, the cathode deposit must be stripped after 12-h intervals to avoid low yields caused by short circuits between cathode and anode. The current yield is $\approx$ 93 %; the energy consumption is 1250 kWh per tonne of cadmium cathode sheet deposited. Careful operation and the use of hide glue and sodium silicate allow cadmium of high purity to be produced. Typical impurity levels in electrolytic cadmium sheet are 5 – 10 ppm Cu, 15 – 20 ppm Pb, 5 – 10 ppm Tl, and 5 ppm Zn.

Some sheet is used as is. Otherwise, it is melted under a cover of sodium hydroxide to prevent oxidation and to reduce the amount of zinc. The molten metal is poured into molds to produce marketable shapes.

2.4.4. Distillation

After mixing with a reducing agent such as pulverized coke, the cadmium sponge can be briquetted. The briquettes can be distilled under atmospheric pressure to a raw metal still containing thallium and zinc. These impurities can be separated from the fused metal by addition of ammonium chloride and caustic soda.

Distillation under reduced pressure avoids a number of disadvantages of distillation at atmospheric pressure. The differences between the vapor pressure of cadmium and those of the most important accompanying elements allows Preussag (Federal Republic of Germany) to produce a 99.99 % pure metal in a single step. The raw cadmium can contain up to 3 % lead and thallium as well as 1 % copper [11]. Every hour, 100 kg of pure cadmium is produced at a distillation pressure of 0.7 – 2.7 kPa and a temperature of 420 – 485 °C. The presence of thallium, the most volatile impurity, at a concentration exceeding 10 ppm in the distillate indicates that the distillation is not functioning properly.

The cadmium distillation process of Hoboken Overpelt, Belgium, allows the processing of cadmium – zinc alloys containing 15 – 20 % Zn. In a two-step distillation procedure, both zinc and cadmium are obtained highly pure (99.995 %) [12].

2.4.5. Other Processes

The cadmium sponge of the Outokumpu Zinc Works contains 0.5 – 2 % zinc, 13 ppm lead, and 15 ppm copper. The briquettes pressed out of this material are smelted with sodium hydroxide. In seven hours 2.2 t of cadmium is obtained using a 110-kW furnace. The refined metal is drawn in a continual casting machine to a cadmium wire, which is then cut to rod. These cadmium rods have a purity of at least 99.95 %; the impurities (max.) consisting of 20 ppm Cu, 10 ppm Zn, 5 ppm Tl, 5 ppm Fe, and 15 ppm Pb [5].

The removal of cadmium from solution by ion-exchange has been described [13]. After stripping, the cadmium is processed further by cementation and smelting. Complexation of the cations to give anionic cadmium species allows selective separation of the cadmium even from

copper and iron [14]. Aliphatic carboxylic acids [15] and *o*-aminomethylphenols [16] selectively extract cadmium from aqueous solution.

2.4.6. Recycling

The purpose of the recycling procedures described here is the production of intermediate products – by special procedures – that can then be fed into the normal cadmium production processes.

The recovery of *cadmium – tin alloys*, about 65 % Sn and 35 % Cd, usually begins by dissolving the scrap in nitric acid. The tin stays in the residue as stannic acid. An impure carbonate is precipitated from the cadmium nitrate solution with soda.

The residue and the rejected batches from the production of *cadmium pigments* containing cadmium sulfide and selenide are dissolved in strongly oxidizing acid. The cadmium is recovered by cementation or as the carbonate. A variation of this process is described in [17].

In order to recycle the cadmium from *nickel – cadmium batteries* and similar production scrap, the parts are dissolved in agitated 2 wt % sulfuric acid. A reasonably good separation from the dissolved nickel can be attained by taking advantage of the lower stability of the ammine complexes of cadmium: cadmium can be precipitated from ammonium hydroxide solution as carbonate, whereas nickel remains in solution [18]. Alternatively, nickel can be extracted from the ammonia solution with chelating reagents before cadmium carbonate is precipitated [19].

Sludge from the treatment of cadmium-containing waste water can often be injected directly into the refinery process (Section 2.4.1). Preliminary, conventional wet chemical enrichment is possible but is usually omitted for economic reasons [20]. Several methods for conversion of electroplating waste water to sludge not requiring special handling can be found in [21].

A plant was constructed by Sab-Nife in Sweden for recycling used batteries and scrap at the same location where nickel – cadmium batteries are produced. Cadmium-containing waste and filter dust are leached with acid, and the cadmium is deposited by electrolysis. Used batteries are dismounted in a semiautomatic process. From the iron- and cadmium-containing plates, the cadmium is distilled under a reducing atmosphere at 850 °C and returned to the production department. Even sealed cells can be processed by distillation after the plastic is destroyed by pyrolytic pretreatment in a slightly oxidizing atmosphere [22].

2.5. Quality Specifications and Analysis

The quality of the cadmium depends on the production process. However, for 99.99 % cadmium, the following maximum impurity levels are generally accepted [11]: 1 ppm Cu, 5 ppm Pb, 5 ppm Tl, and 2 ppm Zn. For special purposes > 99.9998 % cadmium is available.

The maximum amounts of impurities and the analysis procedures are given in ASTM C-752. Although the classical analytical methods for impurities are still used, atomic absorption spectroscopy is the most common method [23].

2.6. Uses

Cadmium metal is used for cadmium coatings, nickel – cadmium batteries, and to a limited extent for reactor construction (see page 6).

Electrodeposited Cadmium Coatings. Cadmium coatings are superior to other metallic coatings because of their optimal combination of properties: corrosion protection, ductility, frictional behavior, and soldering potential. Cadmium coatings have considerable significance in *automotive construction,* where disk brake calipers, bearing races, screws, nuts, bolts, springs, tubing connectors, contacts, and steering parts are all cadmium plated. In *machine construction and factory construction*, the surface of fastening elements, especially screws, is coated. Although the corrosion protection is most important, the frictional properties are also important. For example, even screws that are extremely tight must last for years and then be removable without difficulty. Precision screws and other connecting elements are subject to similar requirements. In the machines of chemical plants they are subjected to corrosion in addition. Aircraft parts not made from stainless steel are usually cadmium coated.

For the often necessary *attachment of different metals*, such as copper alloys, stainless steel, and titanium alloys to aluminum or magnesium alloys, cadmium coating is an absolute prerequisite to avoid corrosion. Cadmium plating is often required in military procurement contracts to ensure that the weapons and equipment function reliably over many years.

Nickel – Cadmium Accumulators (→ Batteries, Chap. 3.2.). The second most widely used storage battery is based on cadmium and nickel. In the charged state the negative electrode consists of cadmium powder, and the positive electrode consists of nickel(III) hydroxide. As the battery discharges, cadmium hydroxide and nickel(II) hydroxide form. Charging reestablishes the original composition. The starting material for the production of the negative electrode is usually cadmium metal, which is dissolved in nitric acid and then precipitated as cadmium hydroxide. In another technique, cadmium hydroxide is repeatedly precipitated into the pores of sintered bodies, which become the negative electrode. A further variation uses electrodeposited cadmium powder, which is mixed with an electrical conductor such as graphite. A properly designed accumulating system does not release gas, even when overcharged, and can be sealed gastight. This development opened the way for new applications, such as rechargeable accumulators not larger than a single primary cell for use in portable electronic products.

In addition to the general advantages of accumulators, nickel – cadmium cells have a long life and are insensitive to low temperature and storage in the uncharged condition. Nonsealed nickel – cadmium accumulators are used in airplanes; telephone, telegraph, and radar stations; computer installations; and emergency power stations. Gastight cells are used in transportable pocket computers, razors, flashlights, etc.

Other Uses. Cadmium compounds, stabilizers for plastics, and pigments (→ Pigments, Inorganic) are generally produced from cadmium metal. The metal is dissolved in a mineral acid, usually sulfuric acid. Dissolution requires considerable time even at high temperatures. Increasingly, cadmium sheets from electrodeposition are used because they, unlike metal blocks, have a larger surface area and dissolve more quickly. Because they do not have to be melted, production costs are lower. In many cases, the high purity of the sheet allows direct use of the cadmium solution without additional purification, especially as the noble impurities remain as residue.

A small amount of cadmium is converted into cadmium sulfide – copper sulfide *solar cells* (→ Photoelectricity), which directly convert light into electrical energy. The yield at present is ≈ 10 %. A yield of 15 % is thought to be attainable. It is expected that these cells can be produced inexpensively. Other cadmium compounds – cadmium telluride, cadmium selenide, and the combination cadmium sulfide – indium phosphide – have also been tested successfully.

The amounts of cadmium consumed for the most important uses are given in Table 2.

3. Alloys

Numerous binary and tertiary cadmium alloys, often with complicated phase diagrams, are known. For practical purposes, cadmium does not dissolve in molten iron or aluminum. A tabular summary of cadmium alloys is available [24], and there is special literature about cadmium alloys [25]. A number of cadmium alloys, as a rule produced simply by melting, are used industrially. They can be divided by their principal use: solder, electrical conductors, and other.

Solder. Cadmium forms alloys with silver, copper, and zinc that have low melting points and are widely applicable for the hard soldering of metals. The cadmium lowers the melting point. More than 80 % of the cadmium used in alloys is used for this purpose.

Aluminum or aluminum alloys can be soldered to copper, brass, or stainless steel by lead alloys that contain antimony, tin, and 2.6 – 17 wt % cadmium [26], [27]. Similar alloys that contain between 0.6 and 60 % cadmium join glass and ceramics at temperatures under 180 °C [28]. For soldered connections on gold-plated electrical conductors, cadmium-containing zinc – lead – indium alloys are recommended [29], [30]. Occupational-medicine aspects of cadmium-containing soldering are treated in [31].

Electrical Contacts and Conducting Wire. The addition of cadmium or cadmium oxide to silver, often the contact material in electrical switches, reduces the metal loss due to sparking. In addition, the welding tendency is decreased. Cadmium (0.8 – 1 wt %) improves the mechanical properties of copper wire without reducing its electrical conductivity. This is especially useful in the case of the overhead wires supplying power to electrically powered locomotives [32], [33].

Other Alloys. Cadmium is a component of a few bearing alloys based on tin, copper, and aluminum, usually in amounts under 1 %. Wood's alloy and Lipowitz's alloy, which contain between 6 and 14 % Cd, are used as fusible alloys in automatic fire-protection sprinklers and other devices. Cadmium in the form of a 5 % alloy with silver and indium is put to use in the control rods of nuclear reactors because ^{113}Cd has a particularly large neutron capture cross section. A cadmium – selenium – indium alloy is an important component of a white-light laser for optical data processing systems [25].

4. Cadmium Compounds and Complexes

4.1. Properties

Generally water-soluble cadmium compounds are colorless. Aluminum and zinc can be used to precipitate cadmium metal from solutions of cadmium salts. From weakly acid or neutral solutions, cadmium sulfide is precipitated by hydrogen sulfide, sodium sulfide, and sodium hydrogensulfides. The temperature, concentration, and presence or absence of Cl^- determine the color of the precipitate: lemon yellow, orange, or even red. Sodium selenide precipitates black cadmium selenide. Mixed precipitates of cadmium sulfide and cadmium selenide are brown. Sodium hydroxide gives white cadmium hydroxide, which is insoluble in excess hydroxide. The precipitate formed by ammonia redissolves in excess reagent to form the complex $[Cd(NH_3)_6]^{2+}$. This complex also forms when ammonia is added to precipitates such as the hydroxide or oxalate. Sodium carbonate produces insoluble cadmium carbonate. Sodium cyanide reacts with aqueous cadmium solutions to give cadmium cyanide, which redissolves in excess reagent to form $[Cd(CN)_4]^{2-}$. This complex is weak enough that the cadmium can be completely precipitated with hydrogen sulfide. Cadmium solutions react with hexacyanoferrate(II) to give a white precipitate, whereas they react with hexacyanoferrate(III) to give a yellow precipitate. Cadmium sulfite is only slightly soluble and can be precipitated from cadmium solution with sodium sulfite. All insoluble cadmium compounds can be dissolved in mineral acids. A few cadmium compounds fluoresce or phosphoresce, the silicate yellow to rose, the borate rose. Silver- or copper-activated cadmium – zinc sulfide gives colors spread over the entire spectrum.

4.2. Individual Compounds

The properties and uses of numerous cadmium compounds are described in [24]. The following text is limited to the most important industrial cadmium compounds.

Cadmium oxide [*1306-19-0*], CdO, M_r 128.41. The amorphous formis yellow red, brown red, or brown black, the color depending on the particle size and the stoichiometry. It has a density of 6.95 g/cm^3. The amorphous oxide is insoluble in water and bases but is readily soluble in dilute acids, ammonia, ammonium salt solutions, and sodium cyanide solutions.

The lustrous black cubic crystals of cadmium oxide have a density of 8.15 g/cm^3. They sublime at $\approx 700\,°C$. The low specific resistance at $0\,°C$, $5.5 \times 10^{-3}\,\Omega\,cm$, is caused by an excess of Cd^{2+} ions, which makes CdO a semiconductor.

Cadmium oxide is produced by evaporation of cadmium metal and oxidation of the vapor. It can also be obtained by thermal decomposition of cadmium nitrate or carbonate or by oxidation of molten cadmium by an oxidizing agent. Commercial cadmium oxide should be completely soluble in sodium cyanide solution and contain no heavy-metal or sulfur impurities.

Cadmium oxide is used as a catalyst in oxidation – reduction reactions, dehydrogenation, cleavage, polymerization, the production of multiply unsaturated alcohols, hydrogenation of

unsaturated fatty acids, and as a mixed catalyst component to produce methanol from carbon monoxide and water. Further uses include resistant enamels, metal coatings for plastics, heat-resistant plastics, selenium ruby glass, starting material for other cadmium compounds, and stabilizers for poly(vinyl chloride). Cadmium oxide combined with an alkali-metal cyanide is the salt mixture used in the baths for cadmium electroplating. Cadmium oxide is a component of batteries. It is temperature resistant and together with silver useful in heavy-duty electrical contacts. Cadmium oxide improves the behavior of some high-temperature plastics.

Cadmium hydroxide [*21041-95-2*] , $Cd(OH)_2$, M_r 146.43, isa colorless powder with a hexagonal, layered lattice. The precipitation of fine-grained cadmium hydroxide is only possible from nitric acid solution, basic salts often resulting from precipitation from other solutions. In the presence of halogenide ions, X^-, the complex $[CdX_4]^{2-}$ forms. In fact, precipitation of $Cd(OH)_2$ can be prevented by a high concentration of alkali-metal chloride. Cadmium hydroxide is a component of cadmium – nickel accumulators and silver – cadmium batteries. Cadmium hydroxide often replaces the oxide as the starting material for other cadmium compounds.

Cadmium carbonate [*513-78-0*] , $CdCO_3$, M_r 172.42, has a density of 5.3 g/cm^3. (The density of $CdCO_3 \cdot H_2O$ is 4.3 g/cm^3.) The white crystalline powder with an orthorhombic lattice of the calcite type decomposes above 360 °C. Often precipitation with sodium carbonate produces hydroxy products, which contain water difficult to remove. Cadmium carbonate is a starting material for the production of cadmium pigments and other cadmium salts.

Cadmium chloride [*10108-64-2*] , $CdCl_2$, M_r 183.32, has a density of 4.05 g/cm^3. The colorless, lustrous orthorhombic crystals, which melt at 568 °C to a liquid that boils at 967 °C, are slightly soluble in water. The hydrates are $CdCl_2 \cdot H_2O$, $CdCl_2 \cdot 21/2\,H_2O$, and $CdCl_2 \cdot 4\,H_2O$. Cadmium chloride is produced by reaction of molten cadmium and chlorine gas at 600 °C or by dissolving cadmium metal or the oxide in hydrochloric acid, subsequently vaporizing the solution. The salt is used in electroplating. An aqueous solution absorbs hydrogen sulfide. Molten cadmium chloride dissolves cadmium metal. Upon cooling, the metal precipitates.

The significance of cadmium chloride as a commercial product is declining. It occurs, however, as an intermediate in the production of cadmium-containing stabilizers and pigments, which are often obtained from a cadmium chloride solution itself obtained from cadmium metal, oxide, hydroxide, or carbonate.

Cadmium nitrate tetrahydrate [*10325-94-7*] , $Cd(NO_3)_2 \cdot 4\,H_2O$, M_r 308.49, has a density of 2.46 g/cm^3. The small colorless deliquescing crystals readily dissolve in water. They have a *mp* of 59.9 °C, and the liquid has a *bp* of 132 °C. There are three hydrates, including the tetrahydrate, and the anhydrous salt (stability ranges):

$Cd(NO_3)_2 \cdot 9\,H_2O$ (−16 to 3.5 °C)
$Cd(NO_3)_2 \cdot 4\,H_2O$ (3.5 to 48.7 °C)
$Cd(NO_3)_2 \cdot 2\,H_2O$ (48.7 to 56.8 °C)
$Cd(NO_3)_2$ (> 56.8 °C)

Cadmium nitrate is produced by dissolving cadmium metal in nitric acid, purifying if necessary, concentrating, and crystallizing. It is used for the production of red lusters in glass and porcelain and in cadmium – nickel sinter plates of storage batteries.

Cadmium sulfate [*10124-36-4*] , $CdSO_4$, M_r 208.46, 4.7 g/cm^3. The melting point of the anhydrous salt is 1000 °C. Anhydrous cadmium sulfate is produced by melting cadmium with ammonium or sodium peroxodisulfate. A saturated aqueous solution contains 76 g $CdSO_4$ per 100 g of water at 0 °C, 77.2 g at 20 °C, 69.4 g at 74.5 °C, and 58.0 g at 100 °C.

$CdSO_4 \cdot 8/3\,H_2O$ [*7790-84-3*], M_r 256.52, ϱ 3.09 g/cm^3. The colorless monoclinic crystals, which effloresce in air, are soluble in water (see above). This hydrate melts at 41.5 °C in its own water of crystallization, converting to the monohydrate.

Cadmium sulfate monohydrate [*13477-20-8*], $CdSO_4 \cdot H_2O$, M_r 226.48, ϱ 3.79 g/cm^3, which is the form usually marketed, is produced by evaporating a cadmium sulfate solution above 41.5 °C.

Cadmium sulfate is used in electroplating and as a starting material for pigments, stabilizers, and other cadmium compounds that can be precipitated from aqueous solution. It is used to produce fluorescent materials and in analysis. A cadmium sulfate solution is a component of the Weston cell, which has an almost constant voltage of 1.0186 V.

Cadmium cyanide [*542-83-6*] , $Cd(CN)_2$, M_r 164.448, ϱ 2.226 g/cm^3, is cubic and isostructural with $Zn(CN)_2$. The solubility in water is 17 g per liter at 15 °C. The solubility in sodium cyanide solution is greater because tricyanocadmium ions, $Cd(CN)_3^-$, form. Cadmium cyanide is produced from dilute cyanic acid and cadmium hydroxide by evaporation or by precipitation from a concentrated solution of cadmium salt and alkali-metal cyanide. Cadmium cyanide and its mixtures with an alkali-metal cyanide are used in electroplating. Cadmium cyanide baths for the electroplating of cadmium metal coatings have the advantage that they are easy to work with. Metal removed from the solution as electroplate is replaced by dissolution of the cadmium anode. These cadmium anodes should be at least 99.95 % pure.

4.3. Storage and Transportation

The labeling for transport of cadmium compounds in the Federal Republic of Germany and the European Economic Community are similar [34], [35]. The rules specify the use of certain symbols and directions for safety precautions. The international provisions for sea and air transport have been made compatible in 1984 [36], [37], although special regulations for individual lands are often still very different. Frequently there are even different provisions for the various types of transportation or routes.

5. Environmental Protection

Cadmium has been ubiquitously distributed in the natural environment for millions of years, and information about this natural distribution in soil and water can be found in general literature, e.g., [24]. Industrial production of cadmium has affected the total distribution in soil and water only insignificantly, although in some restricted areas environmental problems have developed.

More than 90 % of the total nonsmoker intake of cadmium is reported to be through food (see Chap. 7). All sources of cadmium that contaminate cultivated soil, whether by air, fertilizer, or water, should be reduced as much as possible.

Cases of cadmium poisoning caused by the contamination of the environment are described in page 15.

5.1. Emission

Cadmium emission in the Federal Republic of Germany is given in Table 1. Summaries for the United Kingdom [38], the European Economic Community [39], and the United States [40] are difficult to compare because different parameters have been selected. However, this literature cites its sources, so comparison based on tabulations in these sources is possible. Data about industrial emission in the European Economic Community and extensive discussion of the technologies to reduce emissions have been collected [41].

5.2. Waste Water

Cadmium ions are normally separated from sewage by precipitation with an alkali-metal hydroxide or carbonate, with subsequent separation of the sediment. The required limit of 1 mg/L, however, is only attainable when the pH is adjusted to 9.5 or higher, and the precipitate is thoroughly separated from the solution. New regulations go even further and the "Cadmium Guidelines" for the European Economic Community require concentration limits of 0.3 – 0.5 mg/L after 1986 and $\leqq$ 0.2 mg/L after 1989 [42]. These limits can only be met by manufacturers and consumers with special methods [41]. Especially useful for producers of cadmium and cadmium compounds are the coprecipitation of cadmium in so-called collectors and subsequent filtration or special treatment during production and before combination with cadmium-free waste water. In special cases, ion exchange, precipitation, for example, with a sulfide compound, or electrolytic separation is

Table 1. Cadmium emission in the Federal Republic of Germany

Source (Year)	Emission, t/a			
	Air	Soil	Water	Total ∗
Production of Cd metal and recycling (1980)	5 – 7	–	62	69
Pigments (1980)	0.17	–	1.2	1.4
Stabilizers (1980)	0.05	–	0.18	0.23
Electroplating (1981)	–	–	0.7	0.7
Batteries (1982)	0.31	–	0.9	1.2
Alloys (1982)	0.5	–	–	0.5
Glass (1982)	3	–	–	3
Fossile fuels (1982)<	5	–	–	5
Iron and steel (1982)	5	–	–	5
Cement (1982)	0.3	–	–	0.3
Fertilizer (1982)	–	35	0.5	35
Waste-water sludge (1982)	0.1	3.6 – 14.4 ∗∗	–	14
Man-made deposits (1982)	–	–	–	–
Waste burning (1982)	2.9 – 3.8	–	–	3.8
Automobile exhaust (1982)	< 0.5	–	< 0.5	1.0
Total, max.	*26*	*49*	*66*	*140*

∗ Maximum.
∗∗ Forty percent of the 1.8×10^{-6} t of waste water sludge produced each year, or 0.72×10^{-6} t, is used agriculturally. If the sludge contains, on the average, 5 ppm Cd, this corresponds to the minimum estimate, 3.6 t Cd. Twenty ppm corresponds to the maximum estimate, 14.4 t Cd.

used. Clearly the most important factor is the reduction of the amount of cadmium carried into the waste water. Consequently the guidelines of the European Community concentrate on reduction of the amount of cadmium in waste water.

The constant tightening of the standards for waste water purification is intended to prevent excessive concentrations of cadmium in the sludge produced in biological waste-water treatment. When the concentration of heavy metals is too high, the sludge can no longer be used in agriculture. In the Federal Republic of Germany, maximum cadmium content in sludge is restricted to 20 mg per kilogram of dry waste, along with a limitation on the total amount of waste [43]. Similar requirements are in preparation for the European Economic Community.

5.3. Air

Practically all cadmium emission sources are in the form of the oxide because this compound is formed in pyrometallurgical production, high-temperature processing, and combustion, either directly or via the metal. Initially the oxide is finely divided, but these fine particles can be made to agglomerate into coarse grains in suitable apparatus. However, this specialized apparatus is often not practical, and other methods, which also work well enough with fine particles, must be used. The laws vary from land to land. In *TA-Luft* (Technical Regulations for Air) the Federal Republic of Germany requires that not more than 0.2 mg Cd per m^3 of air be released.

Larger gas effluents are usually subject to an electrostatic purification, for example, the removal of particles from gas exhausts of power plants and garbage disposal plants. For low cadmium contents this separation suffices. For high cadmium concentrations filtration is used. The filters can be made from metal screen, ceramic, or a variety of textiles. Regulations and gas release must be carefully adapted to conditions. Washing, especially with Demisters, has proved useful for removal of water-soluble aerosols [44].

5.4. Soil

Cadmium reaches agricultural soil via airborne particles; wastes, particularly sludge; and phosphate fertilizers. The importance of these three has been summarized and described for the Federal Republic of Germany [45].

The normal content of an agricultural field lies between 0.1 and 1 mg Cd per kilogram of soil (0.1 – 1 ppm). Maximum 3 ppm in a 30-cm layer

of top soil is thought allowable, corresponding to 13.5 kg/ha. The contribution to this reservoir per year is 7 g/ha from the air and 6 g/ha from phosphate fertilizer. The removal by harvest is about 4 g/ha. The annual increase is then 9 g/ha. This means that a soil with a content of 4.5 kg/ha, corresponding to 1 ppm, would reach the upper limit after 1000 years.

A number of studies deal with the disposal of sludge [46]. Even then there are still 265 years until the upper limit is reached; therefore, there is time to solve the problem of cadmium emissions. The national regulations for the production of waste-water sediment are tabulated in [47].

However, there are already problems associated with excessive cadmium contents in soil on the grounds of old mining and smelting plants. In the immediate vicinity of the sources of emission, the amount of cadmium in the soil exceeds that thought allowable. Here the use of the adjacent agricultural land must be limited, but there is no large-scale danger. Apparently man-made waste deposits do not create a cadmium source for plants since transfer of cadmium to the soil does not take place.

In addition to concern about the amounts of cadmium [48], the complicated mechanism of transfer from the soil to the plant must be considered. A transport model, from soil into the plant, has been proposed [39].

6. Economic Aspects

Since 1970 the production of the non-communist countries has remained rather constant, 12 – 15 kt/a. The increase in European production was balanced by the decrease in North America. Consumption has remained in equilibrium with production. The amounts of cadmium for various uses have varied since 1970, affected by technical, economic, and environmental factors [49]. The cadmium price from 1970 to the beginning of the 1980s varied strongly, from \$ 0.50 to \$ 4 per pound. The consumption in the Western world between 1970 and 1982 is tabulated in Table 2. The figures are totals of the published statistics for the Federal Republic of Germany, Japan, the United Kingdom, and the United States, which together account for about two thirds of non-communist consumption.

7. Toxicology and Occupational Health

For more than a century there have been many reports on acute poisoning caused by cadmium compounds. Cadmium uptake occurred either via inhalation during occupational exposures or by oral poisoning due to ingestion of contaminated food or beverages [50]. In 1974 it was established [51] that long-term inhalation of cadmium oxide dust could cause a syndrome characterized by damage to the pulmonary and renal systems. Since then many studies have been made in various countries, establishing that occupational exposure to cadmium compounds can cause adverse effects, especially in the kidneys.

During the last decades it was also recognized that cadmium can cause renal effects in the general population. In Japan, a large population is exposed to cadmium via food, especially rice; in one area this resulted in an epidemic of chronic cadmium poisoning with severe bone damage, called *Itai-Itai disease.*

Whereas the exposure levels were reduced considerably in many industries, there is a growing concern about risks for the general population around the world. This is not only caused by emissions from industry. Waste disposal, especially by incineration, the increasing use of phosphate fertilizers, and pH changes in soil and water caused by acid rain are other factors of concern. For more detailed information on different aspects of occurrence, metabolism, and effects of cadmium, see [50], [52–56].

Exposure Levels. The average normal daily intake via food is 10 – 20 µg in most countries; considerably higher values, from 30 to above 200 µg/d, have been reported from certain areas in Japan [50], [52], [54], [55]. The highest cadmium concentrations are found in some basic foodstuffs such as wheat and rice and in liver, kidney, and certain seafoods. Drinking water generally is a minor source. Atmospheric levels of cadmium in rural areas are less than 1 ng/m^3, in urban areas 1 – 10 ng/m^3, and in certain industrialized areas a yearly average of up to 50 ng/m^3 has been found [50]. Atmospheric exposure to cadmium therefore is of minor importance.

Table 2. Consumption of cadmium, t

Use	1970	1973	1976	1979	1982
Plating	3096	3273	3578	3326	2205
Batteries	680	1580	2106	2202	2180
Pigments	2021	3231	2466	2578	1819
Stabilizers	1947	1892	1195	1184	947
Alloys	642	877	519	400	488
Total	*8386*	*10853*	*9864*	*9690*	*7639*

Tobacco may contain 1 – 2 µg Cd per gram, and smoking twenty cigarettes a day has been estimated to result in an inhalation of about 3 µg. Because a large part of that dose will be absorbed, exposure via cigarette smoking may contribute to the internal dose as much as that absorbed from food [50], [52], [55].

Metabolism. In order to understand the toxicity of cadmium some basic facts about the metabolism of this metal must be known.

The fate of inhaled cadmium compounds depends on particle size and solubility. Finely divided cadmium oxides, especially fumes, deposit in the lower respiratory tract; because of their relatively high solubility about 30 % of the inhaled amount is absorbed. Cadmium sulfide and sulfoselenide are relatively slightly soluble, and they are not absorbed to the same extent. (Mucociliary transport to the gut occurs, but the absorption from the gut probably is only a few percent.)

Ingested cadmium generally is absorbed to a few percent [50], [57]. Nutritional deficiencies, e.g., in iron and calcium, will cause higher absorption. Women with severe iron depletion absorbed up to 20 % of the cadmium ingested orally [57].

Cadmium absorbed from the lungs or the gut initially is stored mainly in the liver. Exposure to cadmium induces the synthesis of metallothionein, a low molecular mass, cysteine-rich protein, which strongly binds cadmium but also zinc and copper [58]. The liver has a high capacity to synthesize this protein, and even at very high exposures most of the cadmium in the liver will be bound to metallothionein. The protein breaks down relatively fast, but continuous synthesis ensures that cadmium does not escape to bind to other structures.

In the blood, cadmium is found in the cells and plasma, the concentrations being approximately equal. However, with increasing cadmium levels in the body more cadmium will be found in the cells. In the red blood cells cadmium is bound to several proteins, a major part to metallothionein. In plasma only a minor part is bound to metallothionein. Plasma metallothionein easily passes the glomeruli, and as a protein it will be reabsorbed in the proximal tubules. In the kidneys the protein then breaks down, and cadmium is released. The kidney can also synthesize metallothionein, which ensures that cadmium is trapped in an inert form. However, when the synthesizing capacity is exceeded, cadmium ions will be released and toxic effects may occur.

The cadmium excretion from the kidney is very small. Long retention times in liver and kidney, as well as in other tissue, lead to an accumulation of cadmium in the kidneys from birth to middle age. The newborn is virtually free from cadmium because the placenta is an efficient barrier. The gross biological half-life of cadmium in the body has been estimated to be about twenty years [50].

The average cadmium concentration in the liver of adults is about 1 mg/kg wet weight; the concentration in the renal cortex is about 20 mg/kg in most European countries and in North America [55], [56], [59]. In Belgium higher concentrations, on the average 40 mg/kg in renal cortex, have been reported [60]. The highest concentrations in members of the general population have been found in Japan [55], [56], [59], [60].

Smokers generally have about twice as high cadmium concentrations in the renal cortex (about 25 mg/kg wet weight) as compared with nonsmokers [59], [60].

In the blood the cadmium concentrations in nonsmokers are generally less than 1 µg/L, whereas smokers have up to 5 µg/L [60]. The difference between smokers and nonsmokers is also obvious in the urine. Nonsmokers in Eu-

rope and North America excrete about 0.4 µg/g creatinine, whereas smokers excrete about twice as much [59], [61]. This urinary excretion is related to the level of cadmium in the body and is useful for monitoring general populations as well as most persons that are occupationally exposed to cadmium. The total body burden in adult nonsmokers generally is less than 10 mg [59], whereas that of the newborn is only a few micrograms.

Acute Toxicity. Acute cadmium poisoning by inhalation has mainly been caused by accidental exposure to cadmium fumes. The highest risk is in welding, cutting, or soldering operations when cadmium-containing materials are treated, especially if the worker is unaware cadmium is present. There may be a latent period of up to 24 h after exposure before symptoms occur. Chemical pneumonitis occurs, which may lead to lung edema and general symptoms, in some cases with lethal outcome [50], [55], [62], [63].

The concentration of cadmium in the air has not been measured at the time of accidents. Based on cadmium analysis of lung tissue from people dying after acute exposure it has been estimated that the lethal dose corresponds to 1 mg/m^3 as cadmium fume for eight hours. Concentrations of 0.5 – 1 mg Cd/m^3 for a couple of hours may cause pneumonitis [53]. A short-term exposure limit for cadmium oxide fumes and respirable dust of 0.25 mg Cd/m^3 has been recommended to prevent acute lung reactions [53].

Single *oral* doses of about 10 – 15 mg may cause gastrointestinal disturbances, but the lethal dose is probably several hundreds of milligrams [53], [55].

Chronic Toxicity. The chronic effects after long-term inhalation are mainly seen in lungs and kidneys [50], [51], [55]. In earlier times anemia, anosmia, and yellow lines on the teeth were common among cadmium workers but are uncommon today. Emphysema was a major finding in some earlier studies involving exposure to cadmium oxide fume and dust [50]. Because of the decrease in exposure, lung dysfunction is nowadays rare, and if it occurs the symptoms are mild. Figure 2 shows how air concentrations of cadmium have decreased during the years in a Swedish factory, where emphysema was seen in the 1940s [51], [64]. It has been concluded that to prevent any pulmonary effect of cadmium the time-weighted average concentration of respirable dust in air should not exceed 20 µg/m^3 [53].

Figure 2. Concentration of cadmium in workroom air from 1946 to 1977
Arithmetic means of personal and stationary samples were obtained within seven subperiods. Data covering period IV, 1961 – 1964, are not available.

The critical effect of cadmium is *renal tubular dysfunction.* In 1950 it was discovered that workers exposed to cadmium oxide dust in an alkaline battery factory had an unusual type of proteinuria [51]. The majority of the proteins were of low molecular mass. Studies of renal function showed that the glomerular filtration rate and the concentrating capacity were decreased. The proteinuria in chronic cadmium poisoning is a tubular proteinuria, caused by a decrease in the reabsorption of filtered plasma proteins in the proximal tubules [50].

The urinary excretion of protein was found to be related to exposure time [65]. The critical cadmium concentration in renal cortex was estimated to be 200 mg/kg wet weight [50]. This value was confirmed by further studies [66–68] and is to be compared with the normal concentrations reported in the previous section. A critical urine concentration of about 10 µg of cadmium per gram of creatinine has also been established, which generally is a good indicator of the body burden [50], [67–69].

The best dose – response relationship seems to be between cadmium concentration in the liver, determined by in vivo neutron activation, and the degree of tubular dysfunction [67]. At liver concentrations above 30 mg/kg wet weight proteinuria appeared; this corresponds to a cad-

mium concentration in renal cortex of about 200 mg/kg.

The increased excretion of low molecular mass proteins is regarded as the first sign of renal tubular effects caused by cadmium. This is also consistent with the fact that cadmium primarily is deposited in the proximal tubules, because the cadmium-containing metallothionein is reabsorbed.

At this early stage there are no measurable changes in the excretion of other substances. However, if exposure goes on and the renal levels increase, other functions may be disturbed. In advanced cases of chronic cadmium poisoning the excretion of glucose, amino acids, and phosphate is increased (Fanconi syndrome). Disturbances in mineral metabolism may cause the formation of renal stones. For detailed discussion, see [70], [71].

The *diagnosis* of chronic cadmium poisoning must be based on occupational history, exposure levels in air, levels of cadmium in blood and urine, and protein analysis in urine.

The tubular damage is irreversible, and *prevention* is thus more important than diagnosis. The determination of cadmium in whole blood gives information about recent exposure, but is not always a good indicator of the body burden or risk for renal dysfunction, especially in smokers. Cadmium in urine should be used to monitor this risk. As long as the urinary excretion of cadmium is below 5 µg per gram of creatinine there should be no risk for the kidneys. At concentrations of 5 – 10 µg per gram of creatinine, exposure should be minimized to prevent further accumulation in the kidneys.

Monitoring is also necessary after exposure has ceased. Intensive exposure during relatively short periods may lead to a high cadmium concentration in the liver. Cadmium will then be released from the liver and transported to the kidneys for a long time. The renal concentrations may reach a critical level many years after the last exposure.

The concentration of cadmium in air is seldom of help in evaluating risks. The long biological half-life of cadmium will lead to a continuous increase in renal levels over many years, and past exposure often is more important than present exposure. Changes in workplace exposure during several decades are shown in Figure 2. Figure 3 demonstrates that cadmium blood levels vary greatly. This is most obvious with smokers. The natural cadmium content of cigarettes does not explain this finding, which is caused instead by contamination of cigarettes or pipe tobacco during work and poor personal hygiene, as illustrated in Figure 4 [64].

Figure 3. Cadmium in blood vs. cadmium in air
Arithmetic means of 4 – 5 samples of blood cadmium and 9 – 11 personal samples of airborne cadmium dust for 17 alkaline battery workers. Smokers are represented by the solid circles; nonsmokers, by open circles.

Figure 4. Cadmium in blood in relation to the personal hygiene score
Arithmetic means of five samples of cadmium in blood from nine smokers (solid circles) and of 4 – 5 samples from nine nonsmokers (open circles).

Therefore, it is imperative to prevent smoking in the workshops and the carrying of tobacco in work clothes; such measures will have much more impact than small reductions of cadmium concentrations in air. Dust accumulation must be prevented in the workshop to minimize exposure caused by contamination of work clothes

and hand-to-mouth transfer. The latter may lead to considerable gastrointestinal exposure [72].

The threshold limits for cadmium in air differ among countries, varying from 10 µg Cd/m^3 in Finland to 100 µg/m^3 (total dust) in East European countries. The low values, 10–20 µg/m^3, should prevent renal damage, but as indicated above, smoking and poor personal hygiene may increase the internal exposure.

Carcinogenicity. Cadmium has been implicated as a carcinogenic agent, especially with regard to cancer of the prostate. The evidence is weak and based on deaths from cancer of the prostate. However, this cancer is extremely common among elderly men, and it often does not give any symptoms [73], [74]. There is therefore no evidence that cadmium induces this cancer; diet and hormonal factors are more important determinants. However, it cannot be excluded that in heavily exposed workers cadmium might have affected zinc metabolism in the prostate or caused hormonal changes. It is extremely unlikely that low exposures will have any effect on the prostatic function.

According to animal experiments long-term exposure to cadmium chloride aerosols causes lung cancer in rats [75]. The concentrations of cadmium in air were relatively low, 12.5–50 µg/m^3, but exposures were for 23 h a day. Humans are generally not exposed to cadmium chloride. In the Federal Republic of Germany cadmium chloride has been listed as a carcinogen. There have been a number of studies on the occurrence of lung cancer among workers exposed to cadmium oxide dust, but there are no conclusive results indicating that cadmium oxide causes lung cancer in humans [73].

Poisoning from Contamination of the General Environment. Contamination of the general environment has caused cadmium poisoning in certain areas of Japan [64]. Cadmium levels in rice caused daily intakes of several hundreds of micrograms, which should be compared to the "normal" intake of 10–20 µg in most countries in Europe and North America. The exposure in Japan has caused renal tubular dysfunction of the same type as described in the section on chronic toxicity (page 13). In one area in the Toyama prefecture the cadmium exposure resulted in the development of severe bone damage, Itai-Itai disease. Mainly multiparous women above 40 years of age were affected. The males in the area had tubular dysfunction but generally did not develop the bone disease. The women had poor nutritional status with deficient intakes of calcium, vitamin D, and protein, probably also of iron. Cadmium alone can hardly cause such severe bone changes, but combined with severe calcium deficiency the result became disastrous. It is not likely that Itai-Itai disease will occur again, but as mentioned tubular dysfunction is common in several other areas of Japan.

There are some contaminated areas in Europe, where signs of renal disease have been sought [76], [77]. No definite conclusions can yet be drawn, but the investigated populations had higher cadmium levels than generally found in Europe [77], [78].

Most domestic animals are not at risk for cadmium poisoning. An exception is the horse. Adult horses generally have about five times higher cadmium concentrations in the renal cortex than adult humans in the same area [79].

1. Introduction

Calcium metal was discovered in 1808 independently by Sir Humphry Davy and by J. J. Berzelius and Poutin. Its name derives from the Latin "calx," for lime. Calcium belongs to the alkaline earth elements. Though a metallic element, it is highly reactive and never found in its elemental form in nature. Pure Calcium metal is silvery white. It is oxidized easily and in air forms a white coating; ignited, the metal burns with a brilliant white light and a yellow-red flame.

Calcium is the fifth most abundant element in the Earth's crust and constitutes more than 3 % of the whole. Calcium is the fourth most abundant element in the lunar highlands. Some important, naturally occurring compounds are the carbonate limestone ($CaCO_3$), gypsum ($CaSO_4 \cdot 2\ H_2O$), fluorite (CaF_2), and complex silicates.

2. Physical and Chemical Properties

Calcium [*7440-70-2*], $_{20}Ca$, A_r 40.08; stable isotopes 40, 42, 43, 44, 46, 48. Its major properties are:

Density (20 °C)	1.55
Melting point	838 °C
Boiling point	1440 °C
Specific heat (0 – 100 °C)	0.624 J g^{-1} K^{-1}
Heat of fusion	217.7 J/g
Heat of vaporization	4187 J/g
Thermal expansion (0 – 400 °C)	22.3×10^{-6} K^{-1}
Electrical resistivity (0 °C)	3.91×10^{-6} Ω cm
Thermal conductivity (20 °C)	1.26 W cm^{-1} K^{-1}
Lattice constant (Fcc)	0.5582 nm

Calcium is relatively unstable in moist air, rapidly forming a hydration coating. It can be stored in dry air (less than 30 % R.H.) at room temperature. Calcium reacts spontaneously with water to form $Ca(OH)_2$ and hydrogen gas; when finely divided, it will ignite in air, burn at a high temperature and produce a nitride.

One of the alkaline earth group of metals, group 2, calcium exists in the face-centered cubic (fcc) form at room temperature, transforms into a body-centered cubic (bcc) structure at 448 °C, and melts at 838 °C.

The predominate stable isotope of calcium is ^{40}Ca. Calcium exhibits only one valence state, +2, in all of its reactions. It is slightly less reactive than barium and strontium in the same series. Calcium is a very ductile metal and can be formed by casting, extrusion, rolling, etc. Table 1 presents mechanical properties of calcium.

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a04_515.pub2

Table 1. Mechanical properties of calcium metal

Mechanical properties	Annealed	Cold worked
Tensile strength, N/mm^2	4800	11500
Yield strength, N/mm^2	1370	8500
Elongation, %	51	7
Modulus of elasticity, MN/mm^2	2.2 – 2.6	
Hardness, Rockwell B	16 – 18	

Calcium is noted for its high reactivity, especially the high heat of formation of some of its compounds. This property enables calcium to be used as a reducing agent in the preparation of metals such as chromium, thorium, zirconium, and uranium. Examples are given in Table 2.

Table 2. Heats of formation ΔH_f of calcium compounds

Compound	CAS registry no.	ΔH_f, kJ/mol
$CaBr_2$	[*7789-41-5*]	– 675.3
$CaCl_2$	[*10043-52-4*]	– 795.5
CaF_2	[*7789-75-5*]	–1215.4
CaH_2	[*7789-78-8*]	– 188.8
CaI_2	[*10102-68-8*]	– 535.1
Ca_3N_2	[*12013-82-0*]	– 432.1
CaO	[*1305-78-8*]	– 636.0
CaO_2	[*1305-79-9*]	– 659.4
Ca_3P_2	[*1305-99-3*]	– 504.5
CaS	[*20548-54-3*]	– 482.7

The low density and relatively low electrical resistivity make calcium one of the most efficient electrical conductors on a mass basis. At 20 °C, calcium conducts 16.7 % more electricity than aluminum, and at 100 °C, it conducts 21.6 % more electricity through one centimeter length and one gram mass of the respective metal. Compared to copper, calcium conducts 150 % higher current density at 20 °C, and 197 % higher at 100 °C. Calcium metal is not used as a conductor on Earth simply because it reacts spontaneously when it comes in contact with oxygen, but in the vacuum environment of space, calcium becomes attractive.

3. Production

The electrowinning of metals, the electrochemical production of metals from their compounds, is the oldest industrial electrolytic process. Alkaline earth metals were first extracted by the English chemist Humphrey Davy, using electrolysis of molten salts of sodium hydroxide. In the electrolytic cell, calcium metal collects at the cathode. The metal obtained by this method is typically 98 % pure. By further subliming, it can be purified to levels beyond 99 %.

The major producers of calcium metal are China, approximately 10 000 – 12 000 t/a, primarily at the Shaanxi Zhonghe Special Metal Plant, Hanzhong Shaanxi; Russia, 6000 – 8000 t/a, at the Chepetsky Mechanical Plant, Glazov, Udmurt; the USA, 2000 – 4000 by Minteq International Inc. at Canaan, Connecticut; Canada, at Timminco Ltd; and France, at Pechiney. World capacity was approximately 24 000 t/a in 2005. The USA accounts for about half of the world's consumption of calcium. Total world capacity utilization is close to 80 %.

The process used in Russia is the electrolysis of molten salts of sodium hydroxide; the same process is believed to be used in China. While electrowinning is the more expensive process, it produces a higher purity metal when properly implemented.

In the USA and Canada calcium is produced by thermal reduction of lime with aluminum. The reactants, high-calcium lime of small particle size and aluminum powder, are compacted into briquettes to ensure intimate contact of the reactants. The briquettes are charged into a high-temperature alloy retort. The open ends of the retort protrude from the furnace and are cooled by water jackets to condense the calcium vapor. The retorts are then sealed and the reaction vessel is evacuated to 0.1 Pa or less; it is then heated to 1200 °C. The reaction proceeds for approximately 8 h, the vacuum is broken, and the condensed, 23 – 34 kg pieces of calcium metal, known as crowns, and calcium aluminate residue are removed The aluminum reduces the lime producing calcium metal vapor. The calcium then is removed from the reaction by condensation, thus allowing the reaction to continue in the desired direction. Limestone $CaCO_3$ is quarried and calcined to form calcium oxide. The calcium oxide is then ground and dry-blended with the desired amount of finely divided aluminum. This mixture is compacted into briquettes for reactants then placed in horizontal tubes, i.e., retorts, made of heat-resistant steel and heated to 1100 – 1200 °C at a pressure less than 13 Pa. The commercial-grade metal resulting from this process is suitable for most industrial applications such as steelmaking.

A further vacuum distillation step is required to obtain high-purity calcium metal, used in more specialized refining applications such as the production of neodymium for magnetic alloys. This second operation reduces the level of contaminants. Commercial-grade calcium is placed at the bottom of a large vertical retort made of heat-resistant steel; the vessel has a water-cooled condenser at the top. The retort is sealed and evacuated to a pressure of less than 6.6 Pa; the bottom is heated to 900 – 925 °C. Calcium distills to the condensing section and leaves behind less volatile impurities. Table 3 shows the purity after the first and second purification steps.

Table 3. Chemical analysis of typical commercial and redistilled calcium

Element	Commercial grade, wt %	Redistilled grade, wt %
Mg	0.50	0.50
N	0.08	0.02
Al	0.30	0.001
Fe	0.008	0.001
Mn	0.01	0.002
Co	n.a.	0.0002
Li	n.a.	0.0001
Be	n.a.	0.0001
Cr	n.a.	0.0002
B	n.a.	0.0001
Ca and Mg	99.5	99.9

4. Uses

Steelmaking. The major use of calcium is to improve the quality of steel (→ Steel). For decades, calcium-containing ferroalloys have been used as tap-stream additions to the molten metal, or calcium compounds were injected through a refractory lance by using argon as carrier gas. Although the benefits of using pure calcium metal were known, they were difficult to obtain; calcium is highly volatile, boiling well below steelmaking temperatures.

Calcium is important in steel chemistry because it is a strong oxide and sulfide former; furthermore, it has the uncommon ability to alter the oxides and sulfides to give liquid lime aluminates and underformed sulfides. Treatment with calcium modifies the melting point of inclusions, which rapidly float out of the steel; in addition, treatment alters the morphology of any remaining inclusions, rendering them spherical in shape, very small, and finely dispersed. The result is a fundamental quality improvement, especially in castability and the mechanical properties: formability, drawing, impact, tensile, machinability, resistance to cracking and tearing, and improved surface and internal cleanliness. Calcium also improves resistance to hydrogen-induced cracking in line pipe associated with high-sulfur oil and gas pipelines.

In the early 1970s, calcium wire feeding technology was introduced. A steel-clad calcium wire is fed through a delivery system which propels the wire well below the surface of the molten steel. The steel cladding protects the calcium until it reaches a depth where the ferrostatic pressure suppresses vaporization.

The use of metallic calcium to refine steel became common in Japan and the USA in the 1980s. Cored-wire injection technology was applied in ladle metallurgy, tundish, and mold injection for continuous casting. This led to the adoption of calcium injection for improved castability and superior product quality in thin slab casting. This casting technology, which can produce continuous 50 – 70 mm steel slabs, was developed by SMS and MDH in Germany during the mid-1980. Nucor, USA, established the first commercial-scale thin-slab caster in 1989.

Thin-slab casting employs a specially designed nozzle that is susceptible to alumina buildup, develops progressive blockage, serious clogging, and leads to termination of the casting process. Calcium has proved the most effective method to prevent these problems. With appropriate sequential process steps, treatment with calcium allows inclusion-shape control and gives much cleaner steel.

For large-tonnage use and ladle treatment, a wire-lance system combines the advantages of wire feeding, gas control of fluid dynamics, and treatment with pure calcium. This has resulted in the efficient production of improved-quality ultraclean steels.

Maintenance-Free Automotive Battery. In the maintenance-free automotive battery (→ Batteries, Chap. 4.2.2), calcium improves electrical performance and battery life. The antimony – lead alloy used in the conventional lead – acid battery is replaced with a 0.1 % Ca – Pb grid alloy. The calcium in "calcium batteries" refers to the lead alloy used in the production of the grids for plate making. The alloy is typ-

ically still 99 % lead with alloying metals. Calcium alloy grids afford low water loss and low self-discharge.

Calcium improves the conductivity and current capability of the cell; it significantly reduces gassing, permitting the cell to be closed, thus preventing water loss and extending life. The hydrogen overvoltage increases with calcium – lead alloy grids, so at a given rate of overcharge at the same temperature, an antimonial battery will consume more water than a calcium battery. The resulting battery will not require water addition, i.e., maintenance, during its operating life under normal operating conditions. Their lower internal resistance provides a higher charge-rate acceptance and a small increase in performance. The life and performance of calcium – lead batteries is enhanced by tight control of the manufacturing process and the specifications of the grid alloy for the positive plate.

Calcium – lead alloy grids were prone to expansion and cracking that lead to premature battery failure. The use of calcium alloys and roll-hardening the positive grid reduced the problem. A calcium – aluminum alloy forms a eutectic with lead, and rapid solidification of the alloy makes continuous grid making possible.

Lead – calcium alloys have replaced lead – antimony alloys in a number of casting applications. These alloys contain 0.03 – 0.15 % Ca. Aluminum is added to calcium – lead and calcium – tin – lead alloys as a stabilizer for calcium. Adding tin to lead or lead alloys increases hardness and strength, but lead – tin alloys are more commonly used in type metals and solders for their good melting, casting, and wetting properties. Tin gives the alloy the ability to wet and bond with metals such as steel and copper; unalloyed lead has poor wetting characteristics.

Magnet Materials. High-energy-density magnetic materials are produced using calcium (→ Magnetic Materials). Samarium – cobalt magnets with energy products of between 8 and 16×10^4 T·A/m have found applications in miniature transducers and other devices requiring high energy or volume restrictions. The reaction is:

$$3\,Sm_2O_3 + 10\,Co_3O_4 + 49\,Ca\ (g) \rightarrow 6\,SmCo_5 + 49\,CaO$$

The production of neodymium – iron – boron magnets involves the use of calcium metal as a reductant. This is an important development because these magnets have energy products approaching 40×10^4 T·A/m, over twice that of samarium – cobalt. In addition, the availability of the raw materials is significantly greater than for samarium – cobalt; both the quantity and stability of raw material supply limited the growth of samarium – cobalt magnets. Therefore, neodymium – iron – boron magnet materials are less expensive to produce.

The energy density is sufficient to permit the replacement of armature windings in motors, transducers, and generators with permanent magnets. The weight of an automotive starting motor was reduced from 3.6 to 1.8 kg; the size and cost of the motor were commensurately reduced as well. This technology is finding extensive applications in automotive, computer peripheral, medical, home appliance, and military markets.

There are two methods of producing the neodymium – iron – boron raw material, a neodymium – iron alloy. One is the calcium thermal reduction method:

$$NdF_3 \text{ or } NdCl_3 + Ca + Fe \rightarrow NdFe + \text{byproducts}$$

or

$$Nd_2O_3 + Ca + Fe \rightarrow NdFe + \text{byproducts}$$

The second method is by electrolysis:

$$NdCl_2 + \text{electricity} \rightarrow Nd_2 + Cl_{2(v)}$$

or

$$NdF_3 + Nd_2O_3 + \text{electricity} \rightarrow Nd + \text{byproducts}$$

The calcium thermal reduction process is preferred. It has the greatest flexibility in producing the basic neodymium – iron and alloy variations. The byproducts are not toxic as they are in the electrolytic process. The calcium process is less capital intensive and readily scaled in production volume to meet market demands.

Iron Making. Injection of calcium wire has been adopted by many foundries for iron treatment. Again, the calcium is used for desulfurization, inoculation spherodizing, and alloying.

Calcium ferroalloys are used in the production of nodular iron castings. In magnesium ferrosilicon, calcium reduces the reactivity, enhances nucleation, and improves morphology. The ratio of calcium to magnesium varies from

0.15 to 0.50. Pieces of the ferroalloy are placed in a protected pocket cut in the refractory lining of the ladle prior to tap. The molten iron is then poured into the ladle where it reacts with the alloy. The treated, nodularized iron is then cast into molds.

In the in-mold process, granularized ferroalloy is placed in a special reaction chamber formed in the channels of the mold. This permits the reaction to occur when the iron is cast; it enhances the effectivity of the ferroalloy and results in improved castings. The process can be automated for high productivity.

Other Applications of Calcium and Calcium Compounds. Alloys of calcium also are used to deoxidize magnesium, to strengthen lead electrodes, and to produce special aluminum alloys. Calcium is also used to improve the mechanical properties of lead (→ Lead Alloys). A proprietary process for improving the integrity and formability of the lead used in yacht keels was developed in Australia.

In the *debismuthizing of lead* by the Kroll-Betterton process, calcium metal is combined with bismuth which then floats out in a dross:

$$3\,Pb_3Ca + 2\,Bi \rightarrow Bi_2Ca_3 + 9\,Pb$$

Lead ores are thus refined to commercial soft lead with 0.02 % or less Bi (→ Lead).

Calcium metal is reacted with zirconium fluoride to refine *zirconium*; the high heat of reaction melts the zirconium. The zirconium ingot produced by this method is remelted under vacuum for purification. The resulting metal is leached with acetic acid to remove the lime produced as a byproduct of the reaction.

Uranium fluoride or oxide can be reduced with calcium. To produce *thorium* and *uranium*, the oxides are mixed with a stoichiometric excess of calcium and reduced under an atmosphere of argon. Auergesellschaft during World War II made the uranium metal for the atomic bomb project by using metallic calcium to reduce uranium oxide to uranium metal. In 1945 the Russians dismantled and took the calcium plant to Russia for refining uranium. Calcium produced in China was used in obtaining nuclear materials as well.

Calcium metal is readily hydrided for use as a portable source of *hydrogen gas*. It also is used in the production of the B-complex vitamin calcium pantothenate [*137-08-6*].

Precipitated calcium carbonate is used to replace wood pulp in paper and as an antacid.

Many calcium compounds are used in the foodstuffs, pharmaceuticals and medical industries. Calcium lactate $Ca(C_3H_5O_3)_2 \cdot 5\ H_2O$, calcium diphosphate (phosphate of lime), $CaHPO_4 \cdot H_2O$, and tricalcium phosphate $Ca_3(PO_4)_2$ are used to supply calcium and phosphorus to foods. The last-named also finds application as a polishing agent in dentifrices and as an antacid. Calcium lactobionate, a white powder, provides a suspending agent in pharmaceuticals.

Calcium monophosphate, $CaH_4P_2O_8 \cdot H_2O$ is used as a leavening agent in baking. Anhydrous monocalcium phosphate $CaH_4(PO_4)_2$ is used in pre-mixed flour mixes.

Calcium sulfite $CaSO_3 \cdot 2\ H_2O$ provides a bleach for paper pulp and textiles. As a bleach, it is a disinfectant.

Calcium silicate $CaO \cdot SiO_2$ is used as a reinforcing agent in rubber. This compound also helps manipulate the viscosity of liquids, commercially as a filler in paints and coatings. In coatings it modifies the reflectivity resulting in reduce sheen, a matte surface. Calcium metasilicate $CaO \cdot SiO_3$ (wollastonite) is used as a brightener for paints and paper coatings, a filler for plastics, a coating for welding rods, and for electrical insulators, tile, and ceramics.

Calcium acetate $Ca(C_2H_3O_2) \cdot 2\ H_2O$, (known as lime acetate and vinegar salts) is employed in liming rosin and the manufacture of metallic soaps and synthetic resins.

Limestone is an essential element in Portland cements. Oyster shells ($CaCO_3$) are a commercially important source of calcium for animal feeds.

5. Occupational Health and Safety

Calcium metal reacts with water and acids to form hydrogen gas, calcium oxide and calcium hydroxide; the reaction is exothermic. If calcium metal contacts moisture in the eyes, on the skin, or in the respiratory tract, severe corrosive irritation may result. Inhalation of dust or fume may cause severe respiratory irritation, cough, difficulty in breathing, and chemical pneumonitis. Contact with skin causes irritation and possible corrosion damage.

The substance is severely irritating to the eyes and may injure eye tissue if not promptly removed.

Ingestion may cause acute irritation or burns to the mouth, throat, and stomach; calcium may cause vomiting. Pre-existing chronic respiratory, skin, or eye diseases may be aggravated.

The symptoms of inhalation include severe irritation of respiratory tract. Skin and eye contact symptoms are severe irritation.

There are no known adverse health effects resulting from long-term exposure to calcium metal

First Aid. *Inhalation:* Remove to fresh air. If breathing is difficult, give oxygen. Seek immediate medical attention.

Skin contact: Remove calcium metal immediately with a dry cloth. Wash the area with large amounts of water until all the chemical is removed.

Eye contact: Immediately flush eyes with running water for 15 min. Lift upper and lower eyelids occasionally. Get immediately medical attention.

Ingestion: If victim is conscious, give large amounts of water to dilute the alkali. Do not induce vomiting. Never give anything by mouth to an unconscious person.

Note to physician: All treatment should be based on observed signs and symptoms of distress in the patient. Consideration should be given to the possibility that overexposure to materials other than calcium metal may have occurred.

Firefighting Measures. *Extinguishing method:* Do not use water, foam, or halogenated hydrocarbons such as Halon or carbon tetrachloride to extinguish fire. Use only graphite powder, soda ash, powdered sodium chloride, or an appropriate metal-fire-extinguishing dry powder, such as Met-L-X. For large fires, withdraw from the area and let the fire burn.

Firefighting procedures: Firefighters should wear self-contained breathing apparatus with full face piece operated in the pressure-demand or positive-pressure mode. Firefighters should move containers from the fire area if this can be done without risk. Do not use water or foam. Use dry powder only.

Fire and explosion hazards: Water reacts dangerously with calcium metal and is not recommended as an extinguishing agent for fires that involve it. If water must be used, prevent it from coming into direct contact with calcium metal. If contact is unavoidable, apply the water in flooding amounts to safely absorb the heat that will be generated.

Hazard: Calcium metal is extremely dangerous when wet. Calcium metal forms calcium hydroxide and hydrogen gas resulting in an explosion hazard when wet. Calcium metal forms CaO, quicklime, when it burns. It reacts with wet extinguishing agents such as water, halogens, and possibly carbon dioxide.

Accidental Release Measures. Do not touch spilled calcium metal. Wear protective apparel. Do not smoke or place flame or ignition sources near spill area. Do not allow water to touch spilled calcium metal or to get inside containers. Use a cover, a plastic sheet for example, to prevent water or rain from dissolving spilled calcium metal or to prevent its spreading. Isolate hazard area and keep nonessential personnel away from spill or leak site. Shovel small dry spills into a dry container and cover it tightly. Move containers away from spill to a safe area. Take up small spills with sand or an absorbent and contain as described above. Dike the flow of large calcium metal and water spills with soil, sandbags, or concrete. Keep the waste from entering drains and open sewers. Wear full protective gear.

Handling and Storage. *Storage:* Store calcium metal in a sealed container away from water, acids, or organic compounds. Protect containers against physical damage. Calcium metal will generate heat upon contacting water.

Handling: Avoid damaging container.

Exposure Controls and Personal Protection. *Ventilation:* Provide adequate exhaust ventilation to meet exposure limit requirements. An exhaust filter system may be required to avoid environmental contamination.

Respiratory protection: Calcium metal does not have established exposure limits. Wear a positive pressure air-supplied respirator in situations where there may be a potential for airborne exposure.

Hand protection: Impervious gloves.

Eye protection: Chemical goggles and/or face shield.

Other protection: Wear rubber apron or other impervious clothing to prevent contact with skin.

6. Biological Relevance

6.1. Introduction

Calcium is indispensable for life; it is required for maintenance of structure and metabolism. Examples of the structural role of calcium include the elaborate structure of coral [8], the secreted shells of mollusks, and the internal skeletons of vertebrates. Calcium is also necessary for many biological functions, the most prominent being muscle contraction, nerve conduction, and regulation of blood clotting. To control these functions, all organisms have mechanisms for maintaining critical intracellular calcium levels. Organisms with a circulatory system also have mechanisms to control extra-cellular calcium levels as well as calcium uptake and excretion. The role of calcium in biological systems has been the subject of a number of books [9, 10]. This chapter focuses on the molecular, metabolic and structural aspects of calcium in vertebrate biology.

6.2. Chemical Properties of Ca Important in Biological Functions

Calcium has two properties that render it indispensable for life. First, Ca ions complex with organic compounds, particularly proteins, thereby affecting their function. Second, Ca salts display a wide range of solubility, making it possible for vertebrates to possess a skeleton.

Calcium – Protein/Lipid Interactions. Calcium mediates many biological functions through its ability to bind specifically to proteins and lipids. Calcium binds to proteins by three principal mechanisms. First, it can directly bind the carboxyl groups of glutamic and aspartic acid residues to alter enzyme function. Second, it can interact with specific phosphorylated serine, tyrosine, or threonine residues. Third, specific amino acids that have undergone vitamin K-dependent γ-carboxylation effectively chelate Ca. Proteins may use one or more of these mechanisms to bind Ca. For example, the digestive protein trypsin has a locus of glutamic and aspartic residues that bind Ca, and this changes the conformation of the enzyme to enhance its activity [11, 12]. Osteocalcin (a bone matrix protein) possesses a sequence with three γ-carboxyglutamic acid residues that enable it to bind Ca minerals [13]. The bone matrix proteins osteopontin and bone sialoprotein are rich in aspartic acid, glutamic acid, and phosphorylated serine and/or threonine residues, which permit them to bind calcium phosphate crystals [14 – 18]. Calcium-dependent enzymes can be activated by two principal mechanisms. Many enzymes are activated by binding Ca directly. Other calcium-dependent enzymes do not bind Ca, but are activated by noncovalent association with calcium-binding proteins. Calcium-binding proteins which fulfill this co-enzyme function include calmodulin, annexin, and calcineurin.

To optimize the ability of proteins to bind calcium, the relevant amino acid residues are localized in specific domains which may be conserved between species and throughout evolution. An example domain is known as "EF-hand", which is a single helix – loop – helix structure that binds Ca within the 12-amino acid loop [19]. The proteins possessing EF hand motifs have undergone significant and turbulent molecular evolution. Starting as an archetypal protein containing one EF hand, the genes coding these proteins have undergone duplications, deletions, and retroversions to yield a family of calcium-binding proteins with a wide array of functions and a variable number of EF hands [19 – 25]. A representative calcium-binding protein of this type is calmodulin, which has four EF hands that recapitulate the canonical EF hand sequence observed in slime molds, paramecium, plants, and mammals, including humans [22, 26]. Calcium also complexes with cell membrane phospholipids, which can anchor cell surface-associated proteins on the basis of electrostatic interaction between Ca ion and the negatively charged head groups of cell membrane phospholipids.

Solubility Range of Calcium Salts. Primary calcium phosphate $Ca(H_2PO_4)_2$ is extremely soluble. Secondary calcium phosphate $CaHPO_4$ has a solubility of about 2.0 mM and makes up

about 85 % of the Ca in extracellular fluid. Tertiary calcium phosphate $Ca_3(PO_4)_2$ has a solubility of about 100 μM, and most of it is found in bone in the form of hydroxyapatite [27]. Ultimately, the control of Ca crystallization is determined by these different solubilities and by biological factors, such as calcium-binding and phospholipid vesicles, which can regulate calcium crystal formation.

6.3. Dietary Considerations; Distribution in the Body

The age-adjusted daily calcium requirement is as follows: 0 – 0.5 years, 400 mg; 0.5 – 1.0 years, 600 mg; 1 – 10 years, 800 mg; 11 – 24 years, 1200 mg; 25 and above, 800 mg. The bulk of dietary calcium is derived from dairy and grain products (76 %), the remainder coming from vegetables, protein foods, fruit, sugar, fats, and oils [28]. Lactose enhances the calcium absorption, but fiber and fat, and certain plant constituents reduce its bioavailability. The use of calcium supplements to compensate for poor dietary intake is controversial, since uptake by the gut is highly regulated. Furthermore, the absorption of Ca supplements is dependent on their solubility: the citrate, maleate and lactate salts have high bioavailability, whereas the oxalate is poorly absorbed [28].

Phosphorus is an essential dietary ingredient and a major bone mineral component. Phosphorus is present in most foods, and most adults consume greater than 100 % of required daily allowances [29].

Vitamin D is essential to normal Ca homeostasis and is derived from dietary sources and from *de novo* synthesis in peripheral tissues. The required daily allowance for vitamin D is 10 mg/d; it is found in fortified milk, cod liver oil, and certain fish [30].

The adult human contains 1.0 – 1.3 kg of Ca, about 99 % of which is located in the skeleton, 0.5 % in the teeth, and the remainder in soft tissues and extracellular fluids. Within the plasma compartment, 48 % is found in the free (ionized) form, 48 % is bound to plasma proteins, and 3 % is complexed as citrate, phosphate, or bicarbonate. A simplified schematic of whole-body Ca flux is shown in Figure 1.

Figure 1. Whole body distribution of calcium [31]
Plasma calcium pool is in equilibrium with Ca input (from the intestine, bone and kidney) and Ca output (urine, sweat and feces). There is a steady-state balance in Ca flux to and from bone. While a significant amount of Ca is filtered out by the kidney, most is reabsorbed, and the net loss is usually compensated for by intestinal absorption

6.4. Regulation of Plasma Calcium by Hormones

Cells and tissues have developed mechanisms for compartmentalizing Ca within extracellular and intracellular pools, and can regulate the flux of Ca between these pools very precisely. Hormonal regulation of gastrointestinal absorption, renal absorption, and bone mineral Ca flux provides a system through which plasma calcium levels remain within narrow limits. Three major hormones regulate Ca flux from the gut, kidney and bone.

Parathyroid hormone (PTH) is a major short-term regulator of plasma calcium level and is synthesized by the parathyroid gland. Cell surface receptors for Ca in the parathyroid gland are activated when plasma calcium level falls, resulting in PTH secretion [32]. PTH is also secreted in response to catacholamines, vitamin D, and calcitonin. The net effect of PTH is to increase plasma calcium level by interacting with target cells in the kidney, gut, and bone to stimulate Ca entry into the plasma pool [33].

Vitamin D is responsible for long-term maintenance of plasma calcium level. It is derived from the diet or generated *de novo* form cholesterol following exposure of the skin to ultraviolet

Figure 2. Intestinal cell calcium transport
Two mechanisms allow for transcellular Ca transport. First, Ca is transported through the apical surface by a Ca transport protein (calbindin D_{28K}). It is then transported through the cell bound to Ca-binding proteins, and is extruded into extracellular milieu along basolateral cell surface by vitamin D-inducible ATP-dependend Ca pump in association with Na/Ca exchanger and Na/K pump [37]. Second, calibindin-D_{28K} immobilizes Ca on the cell membrane, which invaginates to form vesicles that carry Ca to basolateral surface. Here, the vesicles fuse with the plasma membrane, discharging Ca into the extracellular milieu [38]. Two processes also allow for paracellular Ca transport. Ca flows passively down a concentration gradient (from 0.5 to 1.25 mM) through structures between intestinal cells called tight junctions that are semipermeable to Ca. In addition, Ca can also be "dragged" by solvent water. By the latter two passive processes, Ca is absorbed, albeit with low efficiency [39].

light [34]. Vitamin D undergoes hydroxylation in the liver to form 25-(OH)-D and then by the kidney to 1, 25-$(OH)_2$-D, which is the major active metabolite regulating Ca homeostasis. Circulating vitamin D_2 has a half-life of about 1.5 d. The major target organs of vitamin D_2 include the gut, kidney, and bone [35].

Calcitonin is a short 32 amino acid peptide secreted by specialized cells in the thyroid gland. Calcitonin secretion is stimulated (or inhibited) by acute increases (or decreases) in plasma calcium concentration. Its plasma half-life is about 10 min. Calcitonin inhibits bone resorption, thus antagonizing the effect of PTH. The role of calcitonin in regulating plasma calcium levels is minor relative to PTH and vitamin D [36].

6.5. Control of Plasma Calcium by Target Organs

In the *intestine*, Ca is absorbed as the free ion with an efficiency of approximately 30 – 32 %. Calcium traverses the intestinal lining either by transcellular flux, which is mediated by calcium-transport proteins or vesicular transport, or a second, passive flux between intestinal cells, known as paracellular flux (Fig. 2).

The *kidneys* are the principal regulators of plasma calcium level, and filter about 10 g of Ca per day. In the renal glomeruli, Ca is filtered out of the blood into the proximal tubule; however, 70 % is reabsorbed in this portion of the kidney by paracellular transport. In addition, about 20 % of the filtered Ca is reabsorbed in the thick ascending limb of Henle by paracellular transport and calcitonin-induced active transport. The remaining Ca is absorbed by the distal convoluted tubes in a PTH- and vitamin D-dependent manner due to enhanced expression of calbindin-D_{28K}. The urinary filtrate thus contains approximately 1 % of the filtered Ca load [39].

Bone contributes to the steady-state plasma calcium level, which is regulated by PTH and vitamin D. PTH promotes bone resorption by activating cells within the bone matrix (osteoclasts) committed to matrix destruction, allowing Ca access to plasma [29]. However, PTH also promotes bone formation, probably due to its action on cells lining bone (osteocytes). Vitamin D has multiple effects on Ca trafficking: it enhances

deposition of Ca into bone by stimulating the maturation of primitive bone cells (osteoblasts) to osteocytes, but also acts in concert with PTH to stimulate osteoclast activity. Thus, PTH and vitamin D act together to increase the rate of bone and mineral turnover without altering net bone mineral content or mass [40].

6.6. Physiology of Intracellular Calcium Trafficking

The optimum intracellular calcium concentration is 0.1 μM, which is 10 000 times less than the extracellular calcium level. Accordingly, cells developed mechanisms to control Ca flux between the extra- and intracellular pools. The major restriction of extracellular Ca to the intracellular milieu is the plasma membrane which has a low passive permeability to Ca. However, the plasma membrane also has Ca channels which allow Ca entry in response to changes in voltage, stretching, or hormonal stimulation [41]. At least one type of channel is tonically active and permits Ca to the extracellular milieu, as described above [42]. In addition, an intracellular tubular structure known as the smooth endoplasmic reticulum (SER) serves as a source of intracellular Ca. A membrane-bound Ca/ATPase transports cytoplasmic Ca into the SER, which lowers cytoplasmic calcium level. In contrast, release of calcium from the SER is mediated by two receptors, one of which is responsive to hormonal stimulation, while the other is activated by the Ca itself [43]. The cytoplasmic calcium level is thus a reflection of the state of activation of the cell. Collectively, calcium-dependent enzymes control nearly every aspect of cell function, including nucleotide metabolism, glycogen metabolism, electrolyte balance, neuromuscular irritability, neural function, muscle contraction, and proliferation.

6.7. Physiology of Bone

Bone is a connective tissue that has the ability to become calcified. Structurally, bone consists of hydroxyapatite deposited within an organic matrix. Hydroxyapatite is hard, rigid, and brittle, and is effective mainly in resistance to compression. However, the organic matrix, over 90 % of which is collagen type I, is flexible and tension resistant. Thus, bone has the tensile strength of cast iron, but has only one-third the weight and is ten times as flexible. Bone is organized into two general types of structures. Compact bone which forms the shafts of the long bones and the outer surface of nearly all other bones, is highly calcified (80 – 90 %). Trabecular bone forms the ends of the shafts of the long bones and most of the bones in the spine, and is 15 – 20 % calcified [44].

Cellular Basis of Bone Formation and Turnover. Bone undergoes continuous remodeling due to the activity of bone-forming cells (osteoblasts, osteocytes), and bone-resorbing cells (osteoclasts). Osteoblasts secrete connective tissue proteins to form unmineralized bone matrix. Mature osteoblasts, known as osteocytes, lie within small cavities that are completely surrounded by bone, and are responsible for bone deposition. These cells are activated by vitamin D, calcitonin, platelet-derived growth factor, transforming growth factor- β, insulin-like growth factor, androgens, and low physiological amounts of glucocorticoids [45]. In contrast, osteoclasts degrade bone, and are activated by PTH, vitamin D, interleukin-1, tumor necrosis factor, and prostaglandin E_1. Conversely, osteoclast activity is inhibited by estrogens [46].

There are two general mechanisms by which bone is laid down. In the first, bone formation occurs in the absence of a pre-existing structure. Primordial cells differentiate directly into osteoblasts, which secrete soluble collagen into the extracellular space. The soluble collagen then self-assembles to form fibrils, which are stabilized by extensive intermolecular cross-linking. Initially, the bone matrix is randomly oriented (or woven), and hydroxyapatite deposition occurs in irregular patches by the formation of matrix vesicles as a result of exocytosis from the plasma membrane of osteoblasts. Mineralization occurs on these vesicles. and as the crystals grow, the vesicle is subsequently destroyed. Bones which are formed by this method include flat bones, such as the skull, jaw, and ribs. The second method of bone formation occurs on a previously existing cartilaginous structure as an initial supporting structure which undergoes initial calcification. Remodeling of this calcified matrix by osteoclasts and osteoblasts eventually

replace the calcified cartilage in the formation first of woven bone, and then compact bone. Mineralization in compact bone occurs within the tightly spaced organic matrix within vesicle formation. This process occurs in the development of the long bones of the legs and arms [47].

Remodeling of bone occurs throughout life. During growth, the midshaft of long bones undergoes growth on the outer surface, and resorption at the inner surface to maintain net bone thickness. At puberty, the growth plates present on both ends of long bone close and prevent further bone lengthening. As bone ages, the organic matrix becomes brittle and weak, and undergoes microfractures. Bone remodeling continuously replaces old matrix with new matrix in a steady-state process of osteoclastic destruction of damaged bone and generation of new bone by osteoblasts. This aspect of bone physiology is the subject of numerous books [44, 48].

Mineralization of Bone. The mineral in bone is hydroxyapatite, and makes approximately 60 – 65 wt % of bone. For the hexagonal form of hydroxyapatite, the content of the unit cell is $Ca_{10}(PO_4)_6(OH)_2$. *In vitro*, hydroxyapatite can be generated by mixing $CaCl_2$ with KPO_4. An unstable amorphous phase (ACP1) is initially formed, followed by the appearance of a second amorphous phase (ACP2), which is less soluble than ACP1. ACP2 then transforms to $Ca_4H(PO_4)_3$, which polymerizes into deficient hydroxyapatite [49, 50]. Other ions can influence hydroxyapatite formation. Fluoride generates two crystal forms: hydroxyapatite covered with fluorapatite, and fluorapatite covered with hydroxyapatite [51]. In contrast, magnesium, carbonate, and cadmium inhibit hydroxyapatite formation by substitution into the apatite crystals, preventing further crystallization. The inhibition of crystal growth by magnesium can be attenuated by fluoride ion [52, 53]. In vivo, hydroxyapatite crystal formation and attachment to collagen is regulated by calcium-binding proteins. Osteopontin and bone sialoprotein initiate and regulate crystal growth and mediate the turnover of bone in areas of growth [54, 55]. In compact bone, hydroxyapatite is maintained by osteocalcin [14, 56, 57] and osteonectin [58 – 60].

6.8. Disturbances in Plasma Calcium Homeostasis

Hypercalcemia. Excessive calcium intake may cause increased calcium levels. However, this is rare, since intestinal paracellular Ca transport is rather inefficient, and at least 2 – 3 grams of additional Ca must be consumed to cause toxicity. Hypercalcemia is usually due to excessive intake of vitamin D, increased PTH secretion (primary hyperparathyroidism), or a consequence of bone destruction secondary to tumor metastasis to bone. Hypercalcemia is manifested by deposition of Ca salts into the heart, blood vessels, kidneys, and skeletal muscles, anorexia, nausea, vomiting, memory loss, confusion, muscle weakness, increased urine excression, and dehydration, and metabolic bone disease (see below).

Hypocalcemia. may be due to inadequate dietary intake of Ca, vitamin D, or insufficient sunlight. The most common endocrine cause is inadequate or nonexistent secretion of PTH (primary hypoparathyroidism). Hypocalcemia is also caused by defects of the PTH receptor in the target cells and is characterized by a resistance to peripheral tissue to PTH rather than by a low amount of active hormone (pseudohyporparathyroidism). The features of hypocalcemia include neuromuscular excitability, which may result in tetany and cardiac conduction defects.

6.9. Diseases of Bone

The strength of bone depends in part on the molecular structure and organization of its constituent mineral crystals in their organic matrix [61]. Most common diseases of bone cause increased propensity for fracture, and are due to a failure in the ability to generate adequate matrix or hydroxyapatite.

Osteoporosis is characterized by a reduction in mineral content per unit volume of bone and is caused by reduced 17- β-estradiol secretion (Type I) or a variety of mechanisms including deficiencies in calcium, vitamins C, D or K, hypogonadism, hyperthyroidism, glucocorticoid excess, rheumatoid arthritis, and immobilization (Type II) [62]. Treatment of osteoporosis includes Ca supplements, vitamin D and bis-

phosphates.[63]. Sodium fluoride is no longer recommended for patients with osteoporosis.

As well as its beneficial effects on the skeleton, calcium supplements may favorably affect serum lipids in postmenopausal women and older men. In addition, there is evidence that calcium consumption is inversely associated with cardiovascular disease in postmenopausal women. In the past, estrogen replacement was considered a primary therapy for the prevention of postmenopausal osteoporosis. Estrogen had the additional advantages of controlling menopausal symptoms and presumptive prevention or delay of cardiovascular disease. However, data now indicates that estrogen-progestin therapy does not reduce the risk of coronary heart disease, and increases the risk of breast cancer, stroke, and venous thromboembolic events.

Osteomalacia is characterized by loss of bone mineral Ca and connective tissue matrix as a result of calcium or vitamin D deficiency. The bony matrix is replaced by poorly ossified fibrous tissue.

Osteogenesis imperfecta is a genetic disease due to defects in the synthesis of Type I collagen, resulting in impaired fibril formation and ossification.

Pagets' disease of bone is caused by osteoclastic hyperactivity, resulting in widespread bone resorption.

Osteopetrosis is characterized by excessive bone ossification due to the relative absence of osteoclasts. Narrowing and obliteration of bone marrow reduces bone distensibility.

Metastatic Calcification. Calcification also occurs in soft tissues, and may have serious consequences. A major cause of soft tissue calcification is a long-standing hypercalcemia. Aberrant calcification can also occur as a consequence of cell death and necrosis. Atherosclerosis is also accompanied by dystrophic calcification, and may be due to the ability of plaque-associated lipids (cholesterol and phospholipids) [64, 65] or bone-related proteins [66, 67] to nucleate hydroxyapatite. Calcification of the vascular wall causes loss of elasticity and disruption of laminar blood flow, which can lead to plaque rupture and thrombosis.

1. Introduction

During the 1980s the important bioregulatory functions of calcium ions (Ca^{2+}; in short: calcium) have emerged. In a normal resting cell the concentration of free calcium is rather low, ranging from 10^{-8} to 10^{-6} mol/L. Calcium concentrations within the cell are effectively controlled by calcium channels and calcium pumps located in the plasmalemma and internal membranes. External stimuli are able to trigger the opening of calcium channels, whereby the internal calcium concentration rises to about 10^{-5} mol/L. Thus, binding of calcium to intracellular calcium-binding proteins is enabled. Activated binding proteins can now interact with target proteins, stimulate their enzymatic activities, and trigger various cellular events. After a kinetic delay, the channels close and calcium pumps restore the initial calcium concentration (Fig. 1). The ubiquitous role of calcium as second messenger in numerous cellular events ranges from muscle contraction in smooth and striated muscle through glycogen metabolism to synthesis and release of neurotransmitters.

Amongst the numerous compounds interfering with calcium pathways by different mechanisms and at different sites, two groups are of major importance: the calmodulin antagonists first described by Weiss [1] and the calcium antagonists first described by Fleckenstein [2]. This review is mainly focused on the molecular, pharmacological, and physicochemical properties of the calcium antagonists.

Figure 1. Scheme of calcium regulation in a eukaryotic cell

2. Molecular Pharmacology

2.1. Sites of Action

Calcium antagonists exert their effects by specific, i.e., receptor-mediated modes of action. The existence of different receptor sites according to the pronounced chemical heterogeneity of calcium antagonistic compounds is experimentally evidenced. Stereoselectivity is one strong indicator for a specific drug action and has been documented for the racemic calcium antagonists verapamil, gallopamil (D 600), prenylamine, and chiral dihydropyridine derivatives.

Calcium channels are multisubunit metalloproteins of a molecular mass of about 180000

(+)-Nitrendipine	Fendiline		
(±)-Felodipine			

[3], [4]. For calcium antagonists of the 1,4-dihydropyridine type receptor sites within the calcium channel have been identified by various groups for smooth muscle [5], [6], heart muscle [7–12], skeletal muscle [13], [14], and brain [9–12], [15–18] with the aid of radioligand binding studies. According to these investigations dihydropyridines exhibit rapid, reversible, saturable, and stereoselective binding to their receptor sites, with high affinities in the nanomolar range. Chemical characterization has revealed heat sensitivity and protein nature of the binding sites probably associated with phospholipids. Furthermore, the binding sites require divalent cations in order to bind dihydropyridines, as demonstrated by the effects of different chelators. Reconstitution of binding occurs by the addition of Mn^{2+}, Ca^{2+}, and Mg^{2+} (in decreasing order). Calcium antagonists were classified according to their binding characteristics to the dihydropyridine binding site [19–21] (Table 1). Class I contains the dihydropyridine derivatives and in addition flunarizine, prenylamine, fendiline, and tiapamil. The latter differ from the dihydropyridines by becoming weaker competitors in the presence of diltiazem whereas the dihydropyridines become more potent competitors. Class II compounds are verapamil, gallopamil, and their enantiomers; they exhibiting biphasic competition profiles representing negative heterotropic allosteric regulators. Class III drugs are positive heterotropic allosteric regulators of the dihydropyridine binding represented by the compound diltiazem. However, it remains to be clarified whether the allosteric sites regulating dihydropyridine binding are identical with the pharmacologically relevant binding sites of verapamil and diltiazem. In the case of the dihydropyridines significant correlations between binding data of a series of nifedipine analogues and their inhibition of mechanical responses was obtained [6]. Ligand binding, therefore, is occurring at the biologically relevant receptor sites.

Further substantiation of the receptor concept for calcium antagonists of the dihydropyridine type was obtained by the development of calcium agonists interacting with the same binding sites. Positive inotropic and vasoconstrictor properties were reported for the compound Bay k 8644, which could be competitively antagonized by nifedipine [22]. By means of patch clamp analysis it could be demonstrated that Bay k 8644 increases the mean opening time of the single calcium channel. The agonistic compound has been obtained by simply exchanging the ester group in position 3 of the dihydropyridine ring by a nitro substituent (see Fig. 3).

Various groups favor *calmodulin* as a receptor candidate for at least some of the actions exerted by calcium antagonists [23–27]. Calmodulin is a ubiquitous calcium-dependent regulator protein, which is involved in numerous Ca^{2+}-mediated cellular events. The pharmacological importance of calmodulin inhibition has first been investigated by the group of B. Weiss, indicating the calmodulin-binding properties of phenothiazines as a biochemical basis of their antipsychotic effects [1]. The key role of calmodulin in the regulation of smooth muscle contraction, the potent vasodilator properties, and the probably intracellular location of at least some sites of calcium antagonistic drug action [28] led to the assumption that relationships between vasodilating and calmodulin-binding properties of some calcium antagonists exist [23], [24], [27]. But only in fendiline and prenylamine, binding constants in the micromolar range were found. The comparably weak binding of verapamil and diltiazem probably excludes a contribution of calmodulin inhibition to the vasodilating properties of these compounds.

The effects of calcium and calmodulin antagonists on the calmodulin-dependent contraction of chemically skinned vascular smooth muscle from rabbit renal arteries were investigated [29]. According to these experiments the vasodilator properties of calcium antagonists cannot be explained by interference with the calmodulin system. Thus, the pharmacological importance of calmodulin inhibition for smooth muscle relaxation by calcium antagonists remains to be clarified by further investigations; however, a subclassification of calcium antagonists based on their differing potency on calmodulin-regulated enzyme activities was developed (Table 2).

Table 2. Subclassification of calcium antagonists, CaM=Calmodulin

Anti CaM activity with putative functional importance	Weak anti CaM activity	Inhibition of CaM and target enzymes
Prenylamine Fendiline Bepridil	Verapamil Diltiazem	Dihydropyridine derivatives

2.2. Structure – Activity Relationships

Beyond stereoselectivity one of the most important criteria in elucidating specific drug actions is the existence of clear-cut structure – activity relationships. The number of chemically rather diverse compounds with putative calcium antagonistic properties steadily increases. Some groups therefore try to differentiate between *specific* and *non-specific* calcium antagonists. Experimental evidence for such a classification is derived from electrophysiological [30] and physicochemical investigations [31]. The following correlations between negative inotropic potency and lipophilicity were obtained [31]: the potency of non-specific compounds increases with increasing lipophilicity whereas specific calcium antagonists exhibit an inverse dependence on lipophilicity (Fig. 2).

Consistently, at least in heart muscle, specific calcium antagonists are represented by the compounds verapamil, gallopamil, nifedipine, diltiazem, prenylamine, and fendiline.

The negative inotropic potency of calcium antagonists strongly depends on stimulation rate; the determination of amplitude – frequency relationships is therefore an appropriate criterion to derive qualitative structure activity relationships for these compounds. Figure 3 summarizes the results obtained from investigations of the two most important calcium antagonists verapamil and nifedipine in isolated cat papillary muscle. In nifedipine [32] the following *essential* moieties could be detected: (1) the dihydropyridine ring, (2) the secondary nitrogen in the heterocycle, (3) a space-filling substituent in the *para*-position of the dihydropyridine ring, and (4) an ester group in 3′-position of the heterocycle. The *ortho* nitro substituent and the 5′-ester structure have been shown to be *non-essential.* The position of the substituent on the phenyl ring is of major importance for the drug potency, which decreases from *ortho* through meta to *para* substitution. These results are in good accordance with in-vivo investigations [33] and they have been substantiated by different other groups in intestinal smooth muscle [6] and in vivo for antihypertensive potency [34].

In the verapamil molecule [28], [35–38] the nitrile group [39], both benzene rings, and the tertiary amino nitrogen are *essential* drug moieties, whereas the isopropyl group and the aromatic substituents are *non-essential. Meta* substitution in the benzene ring near the asymmetric carbon is optimal for potency; *ortho* and *para* substitution diminish potency probably because of steric effects. According to extended Hückel molecular orbital calculations the benzene ring and the nitrile group are coplanar in the most stable conformation [35–41]. These results agree well with other in-vivo observations indicating that halogen-substituted derivatives are mostly effective in lowering blood pressure [42].

Rather limited data are available on structure-activity analyses of diltiazem. The chemical requirements for the vasodilating properties of this compound in the anesthetized dog were investigated [43]. This revealed the importance of the amino nitrogen, parallel to that in the verapamil molecule. Also in the case of diltiazem the *N*-dimethyl derivative (secondary amine) as well as quaternization products were either far less active or not active compared to the parent compound. In contrast, ring substitution affected the potency in an opposing manner compared to verapamil. Halogen substitution (strong negative inductive effects) decreases the potency. Carbonyl substituents in the 3-position of the thiaz-

Figure 2. Correlations between lipophilicity (R_M) and negative inotropic potency (log $1/ED_{50}$) of specific calcium antagonists (open circles) and non-specific negative inotropic compounds (closed circles)

Figure 3. Discrimination between essential and non-essential drug moieties of the two calcium antagonists verapamil and nifedipine

epine ring strongly increase the vasodilating potency of diltiazem.

The electronic, lipophilic, and steric requirements for drug – receptor interactions of calcium antagonists have been investigated by means of quantitative structure – activity relationships (Hansch approach) [37]. Correlations of the negative inotropic potency of a series of verapamil and nifedipine derivatives with the respective physicochemical substituent parameters revealed the following results:

1) Steric and lipophilic properties determine the calcium-antagonistic potency of nifedipine.
2) Potency of verapamil derivatives mainly depends on electronic properties, whereas increasing steric bulk of ring substituents could lead to steric hindrance of the drug – receptor interaction.

These results prove the existence of different receptor sites for calcium antagonists.

3. Pharmacodynamics of Calcium Antagonists in Heart and Smooth Muscle

Coronary heart disease, arrhythmias, and hypertension are the main indications for the therapeutic application of calcium antagonists. Antianginal efficacy is based on direct dilatation of the coronary vessels (vasospastic angina) and on a diminution of preload and afterload due to a decreased peripheric resistance (see also, → Antihypertensives). Antihypertensive potency of calcium antagonists is likewise founded on the vasodilator properties on resistance vessels. Antiarrhythmic properties are explained, on the one hand, by impairment of pathologic calcium-mediated slow action potentials and, on the other hand, by their inhibitory action at the atrioventricular node (i.e., supraventricular tachyarrhythmia).

Most calcium antagonists exhibit negative inotropic actions in vitro, i.e., they diminish the contractile force of the isolated myocardium. However, the cardiac output of a heart in situ is not necessarily reduced by these compounds. This fact has been attributed to reflex sympathetic discharge compensating the direct negative inotropic action of calcium antagonists. The mode and site of interference of calcium antagonists with excitation – contraction coupling (e.c. coupling) is well understood. Because e.c. coupling involves a large set of potential-dependent and time-dependent calcium movements, differentiation of calcium antagonists is easily accomplished by investigating the time and voltage dependence of their action.

The time dependence of inotropic drug effects is simply characterized by measuring contraction amplitudes at varied stimulation frequencies as compared to control conditions. This was done for numerous negative inotropic compounds [44–48]. According to their influence on the amplitude – frequency relationship (AFR) one can differentiate the following three groups:

1) drugs preferentially acting at high stimulation frequencies, such as verapamil, diltiazem, tiapamil, and fendiline (inversion of AFR)
2) drugs with a negative inotropic action fairly independent on stimulation frequency as, for instance, nifedipine and prenylamine (parallel shift of AFR)
3) drugs with a preferred action at low stimulation frequencies, such as bepridil and bencyclane (accentuation of AFR)

Correlations between these pharmacological properties and lipophilic parameters (R_M-value) [31] have elucidated an inverse dependence on lipophilicity for group 1 and 2 compounds, whereas compounds of group 3 exhibit a positive correlation with lipophilicity probably consistent with non-specific membrane perturbing actions.

At the cellular level, the antiarrhythmic action of calcium antagonists is based on the inhibitory effects of these compounds on potential-dependent transmembrane ion currents in working myocardium and in pacemaker tissues. In this context sodium- and calcium-mediated fast action potentials in working myocardium have to be differentiated from mainly calcium-carried "slow" action potentials, which occur physiologically in impulse generating and propagating tissue and pathologically in hypoxic myocardial areas.

Electrophysiological studies of calcium antagonists on sinoatrial (SA) and atrioventricular (AV) node are of main clinical relevance for the antiarrhythmic therapy with these compounds (→ Antiarrhythmic Drugs). In *isolated SA nodes,* both (+)- and (−)-isomers of verapamil and gallopamil (0.2 – 1.0 μg/mL) reduce the discharge rate to the point of complete suppression of automaticity; different mechanisms are responsible for the effects. The (−)-isomers (0.3 – 0.6 μg/mL) slightly reduce the slope of the slow diastolic depolarization, causing a more effective depression of the maximum velocity of depolarization (MVD) and of the nodal conduction velocity until partial or complete nodal conduction blocks occur. The (+)-isomers (1 – 2 μg/mL) do not affect MVD or nodal conduction, but obviously shift the threshold voltage for the fast depolarization to less negative voltages.

In isolated SA nodes nifedipine (3×10^{-7} to 1×10^{-6} mol/L) decreases the discharge rate by reducing both the rate of the slow diastolic depolarization and the maximal diastolic potential until intranodal conduction blocks occur.

In humans , calcium antagonists normally have no significant effect on sinus node function. However, in patients with sinus node dysfunction, the same drugs may induce dangerous bradycardia or sinoatrial block. These different effects seem to be at least in part caused by the different responsiveness of the normal and diseased sinus node to changes in automatic tone via the baroreceptor reflex. In the AV node, conduction and refractoriness are prolonged by each calcium antagonist to a different degree. In this regard, gallopamil and verapamil have a very strong effect, whereas nifedipine in normal doses does not influence AV-nodal conductivity, and tiapamil and diltiazem have an intermediate position between these groups.

For excellent reviews on this topic see [49], [50].

Calcium antagonists exhibit highly selective actions in smooth muscle preparations. This is revealed by their preferential inhibition of depolarization-induced responses described for nitrendipine, nifedipine, and verapamil [51–53].

Agonist-induced responses exhibit varied sensitivity to calcium-antagonistic compounds. The sensitivity of calcium antagonists presumably corresponds to the relative extent to which calcium is mobilized through potential-dependent or receptor-operated channels and intracellular stores. Receptor-operated channels may exhibit different sensitivities to calcium antagonists depending on receptor and tissue under investigation. Thus, some agonist-induced contractions have been shown to be equally or even more sensitive to calcium antagonists as compared to potassium-mediated contractions. Equieffective inhibition of norepinephrine and potassium responses by verapamil were shown in the rat mesenteric artery [54]. Corresponding results were obtained for diltiazem in rabbit mesenteric artery [55].

Originally, calcium channel blockers have been defined as specific and competitive antagonists of calcium flow into heart and smooth muscles. Accordingly, mechanical responses and activated calcium uptake are inhibited by calcium antagonists in nearly the same concentration ranges [56–59].

Selective inhibitory action of calcium antagonists in vascular smooth musculature is presumably based on (1) the presence of different mechanisms for activation, (2) the presence of different groups of calcium channels activated by different stimuli, (3) the distinction between calcium channels in different tissues and (4) the distinction between calcium channels in different vascular smooth muscles [60].

Tissue Selectivity. Norepinephrine-induced contractions in rat aorta are more strongly inhibited by nifedipine than by flunarizine, whereas nifedipine is less active in mesenteric artery [61]. Serotonin-induced contractions are highly sensitive to nimodipine in rabbit basilar artery, but insensitive in saphenous artery [63]. One of the most striking examples of tissue selectivity is concerned with calcium antagonists of the piperazine type (cinnarizine, flunarizine). These compounds relax vascular smooth muscle with high potency, but their calcium-antagonistic potency in heart muscle is rather negligible.

Stimulus Selectivity. The strikingly different sensitivities of agonist-induced and potassium-induced contractions to calcium antagonists have already been mentioned. In this context the use-dependent interaction of calcium entry blockers with voltage-dependent channels represents marked differences to the interaction with receptor-operated channels. The phenomenon of use-dependent drug actions has first been detected for local anesthetics [64] in sodium channels and later on for calcium antagonists in heart muscle [65] and in smooth muscle preparations [59].

In addition to the inhibition of calcium entry interaction by calmodulin, the following alternative mechanisms of the vasodilatation by calcium antagonists are proposed: inhibition of cAMP phosphodiesterase [66], stimulation of Na^+- und K^+-activated ATPase [67], or a stimulation of the calcium pump [68]. Calcium antagonists must be differentiated further into subgroups, e.g., according to their effects [69] or to the occurrence of subtypes of channels [70]. The latter could respond to the striking selectivity of cinnarizine [71] and flunarizine [72] for smooth musculature.

The main pharmacodynamic properties of calcium antagonists are summarized in Table 3.

4. Clinical Application

The spectrum of clinical indications for calcium-antagonistic compounds is permanently widen-

Table 3. Differentiation of basic pharmacodynamic properties of calcium antagonists. Data in the last column on tissue selectivity for vasodilator potency (coronary artery, K^+-contracture) indicate the factor by which smooth muscle is more sensitive as compared to heart muscle.

Drug	Negative inotropic action				Use-dependent action		Electrophysiological action		Vasodilating action	
	EC_{50}*, mol/L	Frequency dependence	Stereoselectivity	Active species	Development of negative inotropic effect	Dissociation from specific sites	Negative chronotropic potency	Negative dromotropic potency	EC_{50}*, mol/L	Tissue selectivity

* EC = effective concentration.

ing. But it is not possible to list therapeutic applications that are common to all calcium antagonists. The different therapy spectra of the calcium antagonists reflect the differing molecular modes of action of these compounds. Verapamil, for example, is extraordinarily suitable in the treatment of several forms of dysrhythmias as well as hypertrophic obstructive cardiomyopathy, whereas nifedipine is not indicated in these diseases. Thus, the following brief summary of the main clinical applications should be considered in terms of variant validity for the individual members of the calcium antagonist family. Calcium antagonists have been found to be useful in treating a wide variety of cardiovascular disorders [73]:

Angiospastic angina (Prinzmetal)
Angina pectoris, any type
Dysrhythmias
Arterial hypertension
Left ventricular failure
Acute myocardial infarction
Cardiac preservation
Hypertrophic obstructive cardiomyopathy
Cerebral vasospasm

One of the most prominent indications of calcium antagonists is referred to as vasospastic or Prinzmetal's angina. In stable angina calcium antagonists apparently are not superior to β-blockers. Combination of calcium antagonists with β-blockers has revealed an impressively increased efficacy as compared to monotherapy.

Calcium antagonists are established in the treatment of arterial hypertension [73], especially when complications by coronary heart disease and/or impaired left ventricular performance are involved. In a comparative study on nifedipine and verapamil the acute and chronic effects of these compounds on blood pressure, heart rate, plasma catecholamines, renin – aldosterone, and plasma volume in patients with mild to moderate hypertension were investigated [74]. Both drugs did not induce renin stimulation or fluid retention. Nifedipine, in contrast to verapamil, increased adrenergic activity which favors the combination of this drug with β-blockers. According to the vasodilator properties of calcium antagonists a clinically important observation indicates that vascular smooth muscle shows markedly increased sensitivity with aging [61]. This was also found in hypertensive patients [62].

The first clinical empirical reports on calcium antagonists were concerned with the antiarrhythmic properties of these compounds. Verapamil is now well established as the drug of choice for treating supraventricular tachycardia. Further indications are related to atrial fibrillation and flutter and sinus tachycardia. Diltiazem exhibits antiarrhythmic properties in part resembling the properties of verapamil; doses required to produce antiarrhythmic effects with nifedipine are not achieved in clinical use.

Additional indications for calcium antagonists comprise cardiomyopathy, cerebral vasospasm, and other vasospastic syndromes.

5. General Aspects of Chemistry

From a chemical point of view the calcium antagonists are a most heterogeneous group of compounds. On the basis of structural features and lipophilicities (Table 4) three main subgroups [75], [76] can be differentiated:

1) aralkylamines, e.g., verapamil, gallopamil, bepridil, tiapamil, diltiazem, caroverine
2) 1,4-dihydropyridines, e.g., nifedipine, nicardipine, nitrendipine, nimodipine, nisoldipine, and further derivatives
3) diphenylalkylamines, e.g., cinnarizine, flunarizine, prenylamine, fendiline, perhexiline, terodiline

Table 4. Physicochemical properties of calcium antagonists. The last column refers to the degree of ionization of the respective antagonist at physiological pH (7.4).

Compound	R_M	pK	% ionized
Nifedipine	0.21	–	–
Verapamil	0.33	8.73	95.5
Prenylamine	0.51	9.47	99.2
Fendiline	0.68	9.33	98.8
Diltiazem	0.42	8.06	82.1
Perhexiline	0.89	11.09	99.9
Bepridil	–	9.39	98.9
Tiapamil	0.11	8.48	92.3

The 1,4-dihydropyridines form a rather extensive group of calcium antagonists for which quantitative structure – activity relationships have been proposed (see Section 2.2). They are easily distinguished from the other two groups. Whereas the aralkylamines and

diphenylalkylamines are protonated at physiological pH, most of the dihydropyridines are uncharged at pH 7.4 (Table 4). The lipophilic character is quantitatively expressed by the R_M values determined by reversed-phase TLC. The diphenylalkylamines can be considered as another chemical subgroup with a bulky lipophilic diphenyl moiety separated by two or three carbon atoms from a basic nitrogen atom.

5.1. Aralkylamines

Verapamil and Gallopamil. Verapamil [*52-53-9*] [77], (±)-5-[*N*-(3,4-dimethoxyphen-ethyl)-*N*-methylamino]-2-(3,4-dimethoxyphenyl)-2-isopropyl-valeronitrile, $C_{27}H_{38}N_2O_4$, M_r 454.6; the hydrochloride [*152-11-4*]melts at 139.5 –140.5 °C.

Trade names: Isoptin (Knoll), Cardibeltin (Pharma Schwarz), Cordilox (Abbott), Calan (Searle), Vasolan (Eisai); contain verapamil hydrochloride.

Gallopamil [*16662-47-8*] [77], 5-[*N*-(3,4-dimethoxyphenethyl)-*N*-methylamino]-2-(3,4,5-trimethoxyphenyl)-2-isopropyl-valeronitrile, $C_{28}H_{40}N_2O_5$, M_r 484.6; the hydrochloride [*16662-46-7*]melts at 145 – 148 °C.

Trade name: Procorum (Chemische Werke Minden); contains gallopamil hydrochloride.

Bepridil [*64706-54-3*] [78], (±)-*N*-(3-isobutoxy-2-pyrrolidin-1-yl-propyl)-*N*-phenyl-benzylamine, $C_{24}H_{34}N_2O$, M_r 366.3; the monohydrochloride monohydrate [*74764-40-2*] melts at 88 – 91 °C.

Bepridil is a long-acting (half-life 42 h) antianginal agent with antiarrhythmic properties. The pharmacological and clinical efficacy of bepridil is reviewed [79].

Trade name: Cordium (Organon); contains bepridil monohydrochloride monohydrate.

Diltiazem [*42399-41-7*] [80], *cis*-(+)-3-acetoxy-5-(2-dimethylaminoethyl)-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4 (5*H*)-one, $C_{22}H_{26}N_2O_4S$, M_r 414.5; the hydrochloride [*33286-22-5*]melts at 212 °C (decomp.).

Trade names: Herbesser (Tanabe Seiyaku), Dilzem (Goedecke), Cardizem (Marion); contain diltiazem hydrochloride.

Caroverine [*23465-76-1*] [81], 1-(2-diethylaminoethyl)-3-(4-methoxybenzyl)-1,2-dihydro-2- quinoxalinone, $C_{22}H_{27}N_3O_2$, M_r 365.5, *mp* 69 °C.

Caroverine is being used clinically as a spasmolytic. Caroverine fumarate is now under development (pre-registration) as calcium antagonist. The pharmacological properties are reviewed [82].

Trade names: Spadon (Donau-Pharmazie), Spasmium (Medichemie, CH).

Tiapamil [*57010-31-8*] [83], *N*-(3,4-dimethoxyphenethyl)-2-(3,4-dimethoxyphenyl)-*N*-methyl-*m*-dithiane-2-propylamin-1,1,3,3-tetra-oxide, $C_{26}H_{37}NO_8S_2$, M_r 555.7; the hydrochloride [*57010-32-9*]melts at 167 – 169 °C.

Tiapamil is structurally related to verapamil. It is a calcium antagonist with antianginal, antiarrhythmic and antihypertensive activities. First launch is expected for 1986.

Proprietary name: Larocord (Hoffmann-La Roche).

5.2. 1,4-Dihydropyridines

Nifedipine [*21829-25-4*] [84], dimethyl 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)pyridine- 3,5-dicarboxylate, $C_{17}H_{18}N_2O_6$, M_r 346.3, *mp* 172 – 174 °C. The chemical structures of nifedipine and other dihydropyridines are shown in Table 5.

Trade names: Adalat (Bayer), Procardia (Pfizer), Duranifin (Durachemie), Pidilat (Giulini Pharma).

Nicardipine [*55985-32-5*] [85], (±)2-(*N*-methylbenzylamino)ethyl methyl 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)-pyridine-3,5-dicarboxylate, $C_{26}H_{29}N_3O_6$, M_r 479.5; the hydrochloride [*54527-84-3*] is isolated in two crystalline forms: α-form, *mp* 168 – 170 °C and β-form, *mp* 179 – 181 °C.

Nicardipine hydrochloride is a calcium antagonistic vasodilator with short half-life, being developed for use in hypertension and angina. It was launched 1981 for cerebrovascular insufficiency and hypertension [86].

Trade names: Perdipine (Yamanouchi), Nicodel (Mitsui).

Nitrendipine [*39562-70-4*] [87], (±)-ethyl methyl 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)pyridine-3,5-dicarboxylate, $C_{18}H_{20}N_2O_6$, M_r 360.2, *mp* 158 – 159 °C, acts as a coronary vasodilator with pronounced antihypertensive efficacy. The duration of action is significantly longer than that of nifedipine [88]. Nitrendipine was launched 1985 as a once-daily antihypertensive without tachycardial side effects.

Trade names: Bayotensin (Bayropharm), Baypress (Bayer).

Nimodipine [*66085-59-4*] [89], (±)-isopropyl 2-methoxyethyl 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)pyridine-3,5-dicarboxylate, $C_{21}H_{26}N_2O_7$, M_r 418.2, *mp* 125 °C, differs from nifedipine and nitrendipine by its predominant cerebral vasodilating effects. It prevents the spasm of brain vessels without considerable decrease of blood pressure. Nimodipine is under clinical development and appears effective in treatment after subarachnoid hemorrhage, cerebrovascular insufficiency, and migraine [90].

Trade name: Nimotop (Bayer).

Nisoldipine [*63675-72-9*] [91], (±)-isobutyl methyl 1,4-dihydro-2,6-dimethyl-4-(2-nitrophenyl)pyridine-3,5-dicarboxylate, $C_{20}H_{24}N_2O_6$, M_r 388.4, *mp* 140 – 142 °C. The pharmacological properties of nisoldipine differ substantially from those of nifedipine and nitrendipine. It acts preferentially on vascular smooth muscle, leading to lowering of the total peripheral resistance. Nisoldipine is the most potent vasodilator known to act by inhibiting transmembrane calcium influx. As a powerful and fast-acting vasodilator without significant side effects nisoldipine should be useful in treating cardiac failure and hypertension [92].

Manufacturer: Bayer, first launch expected 1987.

Niludipine [*22609-73-0*] [93], bis-(2-propoxyethyl) 1,4-dihydro-2,6-dimethyl-4-(3-nitrophenyl)pyridine-3,5-dicarboxylate, $C_{25}H_{34}N_2O_8$, M_r 490.6, *mp* 83 – 86 °C, is a nifedipine analogue with greater vasodilatory activity and with less cardiac depression. The results of a clinical trial suggest that niludipine is a safe antianginal calcium antagonist with broad effectiveness for various types of angina pectoris [94].

Manufacturer: Bayer, first launch expected 1986.

Felodipine [*72509-76-3*] [95], (±)-ethyl methyl 1,4-dihydro-2,6-dimethyl-4-(2,3-dichlorophenyl)pyridine-3,5-dicarboxylate, $C_{18}H_{19}Cl_2NO_4$, M_r 384.3, *mp* 145 °C, is a peripheral vasodilator with antihypertensive activity. Compared to nifedipine it appears more potent, shows less cardiodepressive potency, and the effect seems longer-lasting. Felodipine appears to be an active antianginal drug and is effective in the treatment of hypertension and congestive heart failure [96].

Manufacturer: Hässle (Sweden), phase III clinical trials, first launch 1985.

Table 5. Structural formulas of some 1,4-dihydropyridine derivatives

Drug	X	R^1	R^2
Nifedipine	$2-NO_2$	CH_3	CH_3
Nicardipine	$3-NO_2$	CH_3	$(CH_2)_2N(CH_3)(CH_2C_6H_5)$
Nitrendipine	$3-NO_2$	CH_3	C_2H_5
Nimodipine	$3-NO_2$	$CH(CH_3)_2$	$(CH_2)_2OCH_3$
Nisoldipine	$2-NO_2$	CH_3	$CH_2CH(CH_3)_2$
Niludipine	$3-NO_2$	$(CH_2)_2O(CH_2)_2CH_3$	$(CH_2)_2O(CH_2)_2CH_3$
Felodipine	2,3 – Cl	CH_3	C_2H_5

Nilvadipine [*75530-86-6*] [97], (±)-5-isopropyl 3-methyl 2-cyano-6-methyl-4-(3-nitrophenyl)

-1,4-dihydropyridine-3,5-dicarboxylate, $C_{19}H_{19}N_3O_6$, M_r 385.4, *mp* 130 – 131 °C, is a new dihydropyridine derivative and possesses the advantage over nifedipine of having light stability in solution. Compared with other dihydropyridines, the duration of the effects of nilvadipine is 2 to 3 times longer. Nilvadipine will be beneficial in various cardiocirculatory disorders and particularly promising in the treatment of cerebrovascular spasm and angina pectoris [98].

Manufacturer: Fujisawa Pharmaceutical; phase III clinical trials.

Darodipine [*72803-02-2*] [99], diethyl 4-(2,1,3-benzoxadiazol-4-yl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate, $C_{19}H_{21}N_3O_5$, M_r 371.2, *mp* 153 – 155 °C.

Darodipine lowers blood pressure and heart rate without depressing an ejection phase parameter of myocardial contractility. The wide separation between negative chronotropic and negative inotropic effects could present a therapeutic advantage of darodipine [100].

Manufacturer: Sandoz, phase II clinical trials.

5.3. Diphenylalkylamines

Prenylamine and Fendiline. Prenylamine [*390-64-7*] [101], (±)-*N*-(2-benzhydrylethyl)-α-methyl-phenethylamine, $C_{24}H_{27}N$, M_r 329.5, *mp* 38 – 40 °C; the lactate [*69-43-2*] melts at 137 – 140 °C.

Prenylamine: $n = 1$
Fendiline: $n = 0$

Proprietary names: Segontin (Hoechst), Synadrin (Hoechst, UK).

Fendiline [*13042-18-7*] [102], (±)-*N*-(2-benzhydrylethyl)-α-methyl-benzylamine, $C_{23}H_{25}N$, M_r 315.5; the hydrochloride [*13636-18-5*] melts at 204 – 205 °C.

Proprietary name: Sensit (Thiemann).

Perhexiline [*6621-47-2*] [103], (±)-2-(2,2-dicyclohexylethyl)piperidine, $C_{19}H_{35}N$, M_r 277.5; the maleate [*6724-53-4*] melts at 189 °C.

Proprietary name: Pexid (Merrell).

Cinnarizine and Flunarizine. Cinnarizine [*298-57-7*] [104], (*E*)-1-cinnamyl-4-(diphenylmethyl)piperazine, $C_{26}H_{28}N_2$, M_r 368.5; the hydrochloride melts at 192 °C (decomp.).

Cinnarizine: R = H
Flunarizine: R = F

Trade name: Stutgeron (Janssen).

Flunarizine [*52468-60-7*] [105], (*E*)-1-cinnamyl-4-[bis-(4-fluorophenyl)methyl]piperazine, $C_{26}H_{26}F_2N_2$, M_r 404.5; the dihydrochloride [*30484-77-6*]melts at 251.5 °C.

Trade name: Sibelium (Janssen).

Terodiline [*15793-40-5*] [106], (±)-*N*-*tert*-butyl-1-methyl-3,3-diphenylpropylamine, $C_{20}H_{27}N$, M_r 281.4; the hydrochloride[*7082-21-5*] melts at 178 – 180 °C.

Trade name: Bicor (Recip, Sweden).

1. Introduction

Of all the carbides (→ Carbides), calcium carbide [*75-20-7*] is the most important industrially. It is still the basis of the acetylene welding-gas industry where raw materials and energy are available and petroleum is in short supply. Calcium carbide is produced in a number of countries as the starting material for the products of acetylene chemistry. The fertilizer cyanamide (see→ Cyanamides) and derived products are still produced to a limited extent. Besides these classical applications, calcium carbide is used for desulfurization of pig iron and steel, and in foundry technology, where it is mixed with other metal treatment additives.

History. The chemical composition of calcium carbide was first recognized in 1862 by WÖHLER. He carried out a synthesis starting from a calcium – zinc alloy and coal. Before this, various others had prepared calcium carbide in the laboratory, usually making use of the action of an electric arc on coal or coke products in the presence of calcium compounds. Towards the end of the last century the industrial production of calcium carbide in electrothermic furnaces was developed. Independently of each other, MOISSAN in France and MOREHEAD and WILLSON in the United States laid the foundations, in 1885 – 1895. The year 1895 saw the first production carbide furnace, operated by the Willson Aluminum Company, Spray, United States.

In 1897 BERTOLUS proposed the use of multiphase electric current for industrial furnaces. In 1904 HELFENSTEIN constructed a furnace that used a three-phase current with three electrodes. These first furnaces had a power rating of 3000 – 7500 kW, and evenhad provisions for waste-gas recovery (Helfenstein barrier); within fifty years, 40 MW furnaces were in operation.

Modern large electric furnaces, with power ratings up to 60 MW, have Söderberg electrodes and are completely closed so that the carbon monoxide byproduct can be recovered. Development in recent years has been in the direction of reliable, medium-sized closed furnaces more suited to the market situation and available raw material.

An alternative route to calcium carbide is the carbothermic process, which was operated during 1940 – 1960 by BASF in Germany, but has not been used since.

2. Physical Properties

Calcium carbide [*000075-20-7*], CaC_2, M_r 64.10, is colorless and odorless when pure. Owingto the presence of impurities, various colors, from gray to brownish black, occur in technical-grade carbide, at times even violet or red-brown tones. The typical odor of technical-grade calcium carbide is that of phosphine, which is formed in moist air from traces of calcium phosphide. The melting point of pure calcium carbide is 2160 °C [1]; above 2500 °C complete decomposition takes place [2], [3]. Four modifications of calcium carbide are known:

- Phase I: tetragonal, stable between 25 and 440 °C
- Phases II and III: lower symmetry, stable below 440 °C
- Phase IV, face-centered cubic, stable above 440 °C

Commercial calcium carbide is mainly phase I. Phase II is formed in some pure preparations [4–8]. The heat of transformation of calcium carbide at 440 °C is 8.68 J/g [9].

The CaC_2 – CaO phase diagram (Fig. 1) [1] is a simple eutectic system without compound formation or solid solutions; the pure components are not miscible with each other to a significant extent in the solid state. Above the liquidus line there is complete miscibility. Technical-grade calcium carbide has a lower liquidus temperature owing to the presence of impurities.

Figure 1. Phase diagram CaC_2 – CaO

The average specific heat capacity between 20 and 440 °C is 1047 J kg^{-1}K^{-1}; the heat of fusion of pure calcium carbide is 1470 J/g [10].

The standard enthalpy of formation of CaC_2 from the elements at 298 K and the standard entropy of CaC_2 at 298 K are $\Delta H = -59.4$ kJ/mol and $S = 70.3$ J mol^{-1} K^{-1} [11], [12], [13].

The electrical conductivity of calcium carbide depends strongly on the degree of purity and increases with increasing temperature. Values between 100 and 1000 Ω^{-1} have been reported [14].

3. Chemical Properties

Commercially important reactions of calcium carbide are conversion to calcium cyanamide

$$CaC_2 + N_2 \longrightarrow CaCN_2 + C \quad \Delta H^{298} = -289 \text{ kJ/mol}$$

hydrolysis to acetylene

$$CaC_2 + 2\,H_2O \longrightarrow C_2H_2 + Ca(OH)_2 \quad \Delta H^{298} = -128.4 \text{ kJ/mol}$$

and the reaction with sulfur in molten iron

$$CaC_2 + [S]_{Fe} \longrightarrow CaS + 2\,[C]_{Fe}$$

Acetylene is produced smoothly at temperatures below 300 °C. Pure calcium carbide yields 346.89 L of dry acetylene per kg CaC_2 at 0 °C and 101.3 kPa (372.66 L at 15 °C, 101.3 kPa (1013 mbar), saturated with water vapor). At red heat, calcium oxide, hydrogen, and carbon dioxide are formed [15], [16]. The hydrogenation of calcium carbide under pressure produces calcium hydride and methane as well as other hydrocarbons [17].

Calcium carbide is soluble in molten salts, such as lithium chloride, sodium potassium chloride, and calcium chloride fluoride. Various reductions can be carried out in these solutions [18]. Electrolysis of calcium carbide dissolved in a molten salt yields calcium at the cathode and carbon at the anode.

4. Production

The preparation of pure CaC_2 is only of academic interest. The industrial production of technical-grade calcium carbide is based on the reaction of quicklime with carbonaceous materials such as coke and anthracite:

$$CaO + 3\,C \longrightarrow CaC_2 + CO \quad \Delta H^{298} = +465\,\text{kJ/mol}$$

The reaction rate becomes appreciable only above 1600 °C. Above 2000 °C undesirable side reactions become noticeable, especially

$$CaC_2 \longrightarrow Ca + 2\,C$$

$$CaC_2 + 2\,CaO \longrightarrow 3\,Ca + 2\,CO$$

For these reasons, all industrial processes operate between 1800 and 2100 °C and give a technical-grade calcium carbide with a CaC_2 content of ca. 80 %. The remainder is mainly calcium oxide, but there are also other impurities from the raw materials, principally SiO_2 and Al_2O_3.

The energy for the production of the calcium carbide must be introduced at very high temperatures. There are two possible routes:

1) Melting of the carbonaceous material with CaO in a short electrothermic shaft furnace
2) Combustion of carbonaceous material with pure or enriched oxygen in the presence of CaO in a shaft furnace

The development of the second method has now been discontinued after about 50 years because the synthesis gas byproduct can be made more cheaply from petroleum. In Japan, research has been undertaken to combine methods 1 and 2 [19], but all the calcium carbide produced today is manufactured by method 1.

4.1. Raw Materials and Their Preparation

The raw material or burden that is introduced into the electrothermic furnace consists of a carbonaceous component and a lime-bearing component. The physical properties (particle size, particle strength, conductivity, etc.) and the chemical properties (content of volatiles, ash content, etc.) of the raw material depend on the type of carbide furnace and on the desired calcium carbide quality. Smaller open furnaces do not impose such strict demands because during operation the conditions inside the furnace may be observed and corrective action can be taken, either manually or mechanically. With high-capacity closed furnaces, the properties of the raw materials must allow the furnace to be operated without outside intervention for at least a few days.

The grain-size distribution of the raw material must enable the carbon monoxide to escape. In the reaction zone of the furnace the lime dissolves in the carbide melt, while the carbon component reacts as a solid grain to produce calcium carbide in the liquid. Therefore lime with a large grain size can be used without affecting its reactivity, but for the carbon component a finer grain size is usually necessary.

Modern furnaces are fitted with hollow electrodes through which fine-grained raw material can be blown directly into the molten zone. These manufacturing units only impose an upper limit to the grain size; the necessary fineness is obtained by sieving.

Impurities, particularly metal oxides, cause side reactions that waste energy. The principal impurities are iron oxides, SiO_2, Al_2O_3, MgO, and compounds of nitrogen, sulfur, and phosphorus. Oxides of iron and magnesium are completely reduced, the others only partially. The iron combines with silicon to give FeSi, which is liquid at reaction temperatures. It is partly emulsified in the carbide and can be tapped off. The vaporization of magnesium and its oxidation by carbon monoxide in the cooler parts of the furnace lead to buildup of dust and solid incrustations [20]. The oxides SiO_2 and Al_2O_3 are generally dissolved in the carbide – CaO melt along with the nitrides, sulfides, and phosphides formed from the nitrogen, sulfur, and phosphorus compounds.

The following carbonaceous materials are available: coke from bituminous coal or lignite, anthracite, petroleum coke, and charcoal. Coke from bituminous coal is used worldwide for calcium carbide production.

Uncalcined anthracite and petroleum coke can be used only as a part of the charge in a closed furnace. If the volatile content is reduced below 2 % by calcination, they can be used as the sole charge. This is done in South Africa, a country rich in anthracite. Charcoal can be used only in small open furnaces.

Today for closed furnaces coke with a grain size of 3 – 25 mm is used. The fraction below 3 mm is blown in through the hollow electrodes. Small open furnaces can also use coarser grain sizes. Before introduction, the coke must be

dried below 2 % moisture content. Ash content below 15 % is necessary to meet the quality standards for the calcium carbide product in many countries.

The lime-containing component of the raw material mixture is predominantly quicklime. Manufacturing plants with large closed furnaces specify a grain size of 6 – 50 mm, and the material below 6 mm is blown in through the hollow electrodes. For closed furnaces, the magnesium content should be below 2 %. The lime must be burnt so as to be as soft as possible, but resistant enough for transport and storage. This is achievable in modern lime kilns. At the same time the CO_2 content is reduced to less than 2 %.

The calcium hydroxide left behind after acetylene generation from calcium carbide, after granulation or briquetting with calcination, is also a cheap raw material. However, this lime recycling is limited by the build-up of impurities.

Typical examples of compositions of raw materials for calcium carbide production are listed in Tables 1 and 2.

Table 2. Composition of lime for calcium carbide production (wt %)

	New lime	Recycled lime
Total CaO	93.8	89.0
Free CaO	93.6	–
$CaSO_4$	0.4	–
SiO_2	1.3	2.9
Fe_2O_3	0.4	0.4
Al_2O_3	0.5	2.4
MgO	0.8	0.8
CO_2	2.7	3.0
P_2O_5	0.015	0.01
Loss on ignition (CO_2)	0.5	0.5

4.2. Electrothermic Reduction

The raw material mixture is heated to a high temperature in a short shaft furnace with an electric current. Investigations of the reaction have led to the conclusion that it takes place in two steps:

$$CaO + C \longrightarrow Ca + CO$$

$$Ca + 2\,C \longrightarrow CaC_2$$

The principal reaction in the furnace takes place in a $CaC_2 - CaO$ melt. Electric current, energy supply, temperature, and chemical reactions interact in a manner that is not yet completely understood. According to [21] the rate-determining step is the transport of the CaO dissolved in the melt to the surface of the coke grain, where the CaC_2 is formed. This CaC_2 then immediately dissolves in the melt. The liquid calcium carbide is tapped from the bottom of the furnace.

4.3. Furnaces

Carbide furnaces can be divided into various classes according to their electrical supply (single-phase, three-phase), the arrangement of the electrodes (serial, symmetrical), and the means of excluding air (open, half-covered, closed).

4.3.1. Single-Phase Furnaces

High-performance single-phase furnaces were developed in 1928 by MIGUET. This first furnace had a power rating of 15 MW. These furnaces are operated with low voltage and high current; optimal arrangement of the electric circuit produces a power factor ($\cos\varphi$) of up to 0.95.

4.3.2. Three-Phase Furnaces

The majority of today's carbide furnaces are operated with three-phase current. They can be classified according to the arrangement of the electrodes.

Serial. In a serial furnace the center lines of the three electrodes lie in a straight line, or they form an isosceles triangle. Rectangular and oval furnaces were formerly equipped exclusively with package electrodes made from precoked coal; later, rounded rectangular *Söderberg electrodes* were preferred. The serial furnace has advantages over the round furnaces as regards feeding and distribution of the burden and can be operated half covered without any problems. Water-cooled barriers between the electrodes not only provide for even distribution of the burden but also promote cooling of the upper part of the solid material, hence reducing its conductivity.

Table 1. Composition of carbonaceous raw materials for calcium carbide production (wt %)

	Metallurgical coke	Anthracite	Petroleum coke
Fixed carbon	89.0	80.0	81.6
Volatile carbon	0.8	6.0	9.0
Moisture	0.8	8.0	8.0
Sulfur	0.8	0.8	1.9
Ash	9.4	6.0	0.3

The unsymmetrical arrangement of the secondary current conductors leads to an inductive effect and consequently to dead and live phases with respect to the middle phase. Output and electrode consumption differ at the three electrodes owing to the differences in power consumption. (For the theoretical relationships, see [22–25].) Difficulty can occur in discharging the melt at the dead phase; this can be alleviated, for example, by addition of lime. A further disadvantage compared with circular furnaces is the unfavorable ratio of furnace capacity to surface area, which leads to greater heat loss.

Furnaces of this type still exist and are operated at up to 40 MW, sometimes with hollow electrodes (see page 5). However, all modern carbide furnaces are now symmetrical three-phase furnaces.

Symmetrical. In symmetrical three-phase furnaces the electrodes and as far as possible the transformers together with the high current conductors are arranged symmetrically about the center. In a circular furnace vessel the electrodes are situated at the corners of an equilateral triangle [26]. Well-designed circular furnaces have the advantage that high power factors can be achieved. At a sufficiently high power, molten zones are formed at all three electrodes and overlap at the center of the furnace. The tapping points should be situated as near as possible to the electrodes. On account of the high temperature, the furnace wall at the tapping point must be water-cooled or constructed of highly heat resistant material.

4.3.3. Half-Covered Furnaces

According to the equation

$$CaO + 3\,C \longrightarrow CaC_2 + CO\ (g)$$

one mole of CO is produced for each mole of calcium carbide. In the first years of carbide production this gas was simply burnt at the open furnace. Because of the air pollution they cause, large furnaces of this type have largely been retired from service.

In Germany, HELFENSTEIN attempted in 1910 [27] to construct above the linear furnace rooflike covers made of welded, water-cooled steel tubes between the electrodes. These gas collectors can also consist of ceramic material traversed by cooling coils. The liberated gas can be collected in this way. For the symmetrical three-phase furnace the construction of a gas collection hood is more difficult.

4.3.4. Closed Furnaces

Closed three-phase furnaces permit 100 % gas recovery and in normal operation do not cause any pollution of the environment by escaping dust-laden carbon monoxide. A schematic of a typical closed furnace is shown in Figure 2.

Hearth. The hearth consists of a welded steel outer casing stiffened with steel girders and ribs. The horizontal steel sheets are fixed in a ring shape round the hearth for reinforcement. A natural air current should flow around all sides.

The base of the hearth is lined with carbon blocks and rammed carbon to a height of about 1.5 m. The side walls are lined with refractory bricks or rammed refractory material. The region of the tapping point, because of the especially high temperatures, is more strongly constructed or provided with water cooling.

Electrodes. For supplying electrical energy to the molten region of the carbide furnace at ca. 2000 °C, carbon is the only suitable material. The electrodes must have high electrical and

Figure 2. Closed carbide furnace

thermal conductivity and adequate mechanical strength.

The *prebaked carbon electrode*, which was at one time the only type used, has with few exceptions been replaced by the Söderberg electrode, first tried in 1921 [28]. In open rectangular furnaces prebaked packaged electrodes were used. Round electrodes are manufactured up to 1.5 m in diameter and 2.5 m in length. The current density achievable with prebaked carbon exceeds 10 A/cm^2.

The *self-baking Söderberg electrode* consists of a sheet steel cylinder with internal vertical ribs. This casing is filled with electrode paste. Söderberg electrodes are the most economical type of electrode for furnace ratings from about 10 MW upwards. The electrode paste is manufactured from coke, calcined anthracite, or petroleum coke and a tar/pitch binder. The most important property of the paste is freedom from breakage, even under high or variable load and at low consumption. The consumption of the Söderberg electrode is compensated by welding on a new steel casing and filling with new electrode material during furnace operation. The consumption of Söderberg paste can range from

15 to more than 20 kg per tonne of calcium carbide, especially if the electrode is not hollow.

The *hollow Söderberg electrode* has been used increasingly since 1961 [9], [30]. Lime and coke fines are introduced directly into the molten region through a central pipe by a carrier gas such as carbon monoxide or nitrogen. The carbide-forming reaction causes a temperature reduction and cools the tip of the electrode; a reduction of the rate of electrode consumption by up to 50 % is achieved, and cheap lime and coke fines can be used. Prebaked electrodes can also be provided with a central hole and operated as hollow electrodes. Large furnaces with power loads higher than 30 MW should always be equipped with hollow electrodes.

The electrode connection for continuous electrodes consists of water-cooled metal contact clamps, adjusted exactly to the shape of the electrode to ensure optimum transfer of the electric current. Up to ten pressure plates are pressed against the round electrode casing by a water-cooled pressure ring. A remote-controlled slipping device adapts the slipping rate to the rate of consumption of the electrode, so that the baking zone of the Söderberg electrode does not drop below the clamps. Otherwise, burn-through of the casing and breakage of the electrode can occur. The baking zone can be monitored by thermocouples, mechanical sounding, or by measuring the voltage between the casing and a steel rod in the electrode. The electrode length is an important factor for furnace operation and can be measured by mechanical sounding or weighing.

A new development is the modular electrode holder, in which the electrode ribs extrude through the casing into the contact assembly [31]. The contact clamps and pressure ring are replaced by a slipping unit at each rib. There are no radial forces acting on the electrode, and heat removal from the electrode is low.

The *electrical supply* to industry is today exclusively three-phase alternating current.

In the oil-cooled transformers the oil is circulated and cooled indirectly by water. The oil pressure is usually higher than the water pressure to prevent water from entering the oil circuit in the event of any leakage. On account of the occasional violent load alterations of the furnaces, such as may be caused by variable current demand and variable resistance of the burden, the power of the transformer must be controllable with the largest possible load variation. For this purpose motor-driven sequence switches are necessary. The operating voltage of today's carbide furnaces is in the region of 100 – 300 V. The secondary current (up to 150 kA) is carried by water-cooled copper conductors or flexible cables.

A power diagram is used to represent the specific operating conditions of a three-phase furnace. Apart from the negligible ohmic resistance of the high-current cables and the electrodes, this includes the constant, calculable reactance of the transformer, cables, and electrodes, as well as the variable resistance (impedance) of the furnace itself [23–25]. The power must be variable between wide limits for practical operation, e.g., starting up and shutting down the furnace, adjusting the electrical load to suit the conditions in the furnace (temperature, pressure), or today's usual wide-ranging operating schedule for electricity consumption (day/night usage, etc.).

For the single-phase furnace a current regulator is sufficient; for the multiphase furnace, impedance control, i.e., the control of apparent furnace resistance, by setting the immersion depth of the electrodes is necessary.

Certain types of closed hood construction allow for raising and lowering of the feed chutes so that, in addition to supplying the feed material, they can be used to alter the configuration of the surface of the burden and hence the furnace resistance.

4.4. Operation

On start up, the carbide furnace is charged with a layer of coarse coke. Then the electrodes, at a low voltage, are brought towards the coke until contact takes place, which can be seen by the appearance of electric arcs between individual pieces of coke. When the black material is at red heat, the furnace bottom is gradually fed with burden and the power is slowly increased.

Smooth operation of the furnace requires smooth feeding of burden. Any variations in the optimal composition of the burden are usually compensated by addition of lime. This also necessitates a desirable deeper immersion of the electrodes in the melt owing to the low conductivity of the lime. When the electrodes are raised too high, carbide is produced in the upper layers

of the burden, which leads to increased danger of spurting from the melt. The mass of solid material must remain permeable to gas at all times.

Closed three-phase furnaces have numerous feed chutes, which are arranged around the electrodes and automatically supply the burden. Special attention must be paid to the composition and grain size of the black – white mix to prevent any segregation. The feed must above all contain no dust, in order to reduce the danger of crusting. However, if cheap, very impure raw materials are used, crust and slag formation cannot be eliminated, and they appear on the lower electrical connectors and the hood. In such circumstances and also in the case of segregation of the feed materials, short circuits can be produced and can destroy the parts affected. A compromise is necessary between cheap raw materials and avoiding damage to the furnace.

The gas pressure inside the furnace hood should be about equal to atmospheric pressure. A lower pressure causes atmospheric oxygen to leak into the furnace, severe excess pressure leads to carbon monoxide contaminating the environment and can endanger operating personnel.

Where large units or groups of furnaces are in production, the entire furnace operation is usually computer-controlled from a separate control room.

To tap off the calcium carbide, the furnace is opened mechanically or by burning a tapping hole with an electric arc. The tapping electrode is a baked electrode, 10 – 12 cm thick, which is supplied with electricity from its own transformer, a furnace transformer, or both. The molten calcium carbide flows at 1700 – 2100 °C, depending on its purity, through cooled tapping spouts into cast-iron ladles that can be handled on a carousel arrangement or continuous track. Owing to its high melting point and the rapid loss of heat by radiation, technical-grade calcium carbide (80 % CaC_2) solidifies very quickly so that the tapping holes must be kept open either mechanically or manually with steel rods. When tapping is completed, the hole can be closed with a clay plug or plugging carbide is propelled or blown into the tapping hole until it solidifies. The fumes arising from the tapping hole are removed by fume extraction equipment. As these fumes have the character of an aerosol (particle size, 20 % $< 10\,\mu m$), purification is expensive.

During tapping the process operators must be protected from the hot gases, dust, and spurting carbide with the aid of chain curtains, wire netting, and steel shields installed in front of the tapping point. The tapping men wear aluminum-covered fireproof coats, dark glasses, and protective visors, in addition to fire-retardant working clothes.

Modern tapping machines equipped with a hydraulic manipulator can carry out all tapping operations. They are fitted with interchangeable tools such as tapping electrodes, reaming rods, and plugging devices. In this way, the tapping personnel can be reduced to one or two men per shift.

The reduction (especially of Fe_2O_3 and SiO_2) by carbon yields iron and silicon, which react to give ferrosilicon. This FeSi, on account of its appreciably higher density, collects under the carbide melt and normally flows away on tapping the furnace. As the melting point of this alloy is however several hundred kelvin below that of the carbide melt, there is a danger that FeSi could flow through cracks in the extremely hot furnace lining and cause damage in the area surrounding the furnace before it solidifies. In every carbide plant constant attention is paid to this problem.

4.5. Furnace Gas

Composition. The composition of the furnace gas depends on the raw material. If moist coke is used, the hydrogen content increases on account of the water-gas reaction, $C + H_2O \rightleftharpoons CO + H_2$. The result is the same when any appreciable amounts of volatiles in the black material are thermally cracked. Incompletely calcined limestone leads to the production of carbon monoxide as a result of the reaction $CO_2 + C \rightleftharpoons 2\,CO$, which consumes both coke and energy.

A sudden increase in hydrogen content suggests a water leak in the furnace. If the carbon dioxide and nitrogen contents increase, then the hood can no longer be relied upon to be gastight. If atmospheric oxygen enters the furnace hood, combustion occurs and increases the temperature of the cooling water and gas. Explosions are to be expected only on ignition of an unburnt mixture of oxygen and carbon monoxide when the furnace is cool.

A typical analysis of the purified gas (vol %) follows:

CO	80 – 90	CH_4	1
H_2	6 – 15	N_2	2 – 7
CO_2	0.5 – 3.0		

The heat of combustion is ca. 11 720 kJ/m^3 (STP).

Gas Purification. The carbon monoxide obtained from half-covered or closed furnaces must be dedusted. Both dry and wet dedusting methods are used.

In the dry dedusting process, the gas is, e.g., filtered by self-supporting candle filters made of ceramic fibers [33]. Their surfaces are cleaned off-line by jet pulses of previously cleaned gas or nitrogen. A final dust content of < 1 mg/m^3 can be attained. Finally the hot furnace gas is cooled in a heat exchanger. The dust from the filter has the composition 35 – 40 % CaO, 15 – 25 % MgO, 8 % $Fe_2O_3 + Al_2O_3$, 7 % SiO_2, 10 % CO_2, 9 % C and it is difficult to use. Owing to the presence from time to time of soluble cyanide the disposal of dust also is a problem. However, there are methods of roasting that remove cyanide.

In the wet process the gas is passed through several washing towers and sprayed with circulating water. In the last stage, Theisen washers reduce the dust content to ca. 5 mg/m^3 at STP. Cyanide in the slurry is precipitated as an iron complex, and the slurry is separated in thickeners, usually hydrocyclones. The clear liquor that overflows is reused.

4.6. Mass and Energy Balance

A modern large furnace without hollow electrodes requires per tonne of 300-L calcium carbide 950 kg lime (94 % CaO), 550 kg coke (dry, 10 % ash), 20 kg electrode material, and 3100 kWh electricity [26].

The typical analysis (wt %) of a commercial calcium carbide that yields 300 L of acetylene per kilogram of calcium carbide follows:

CaC_2	80.5	Fe	0.2
CaO (free)	12.9	S	0.5
Si	1.3	C	0.3
Al	1.1		

The enthalpy of reaction (ΔH) for such calcium carbide is 465 kJ/mol, corresponding to ca. 2000 kWh per tonne. In practice, for 300-L technical-grade calcium carbide, depending on purity of raw materials, furnace type, and loading, about 3000 – 3300 kWh/t are required. The difference is accounted for by the heat contents of the molten carbide and furnace gas and the heat lost to the cooling systems.

5. Further Treatment

5.1. Cooling

Most carbide plants use the block casting method, in which the liquid calcium carbide is tapped off into a ladle or crucible and solidifies to a block. The block is allowed to cool and is then broken up, ground, and sieved to the required size.

Generally, a cast-iron crucible receives the liquid carbide at ca. 1900 °C from the tapping point. After a short time, a solid crust forms on the walls of the crucible and isolates the iron from the hot liquid core of the block. The heat passing through this crust is then radiated from the iron. To prevent cracking of the crucible, this process is regulated so that the temperature of the iron does not exceed 600 °C, mainly by ensuring that the mass ratio of iron to carbide exceeds 2 : 1. Depending on the power of the furnace, crucibles with a capacity between 0.4 and 2.0 t are used.

For further cooling of the block there are several possibilities. If small molds are used, the block is lifted or tipped from the mold after ca. 2 h and then cools further outside the mold, either on a block transporter, or on steel conveyor belts that transport it to the crusher. The cooling times are ca. 20 h.

Higher power carbide furnaces are generally equipped with crucibles of capacity over 1 t. In one operating procedure the filled crucible is placed in a cooling room, and after 25 – 30 h the contents of the crucible are tipped into the crusher. This procedure has the disadvantage that for a 55 MW carbide furnace, 400 1.5 t crucibles must be ready for use. As the weight of the crucible must be at least twice the weight of the contents, this means an investment in about 1200 t of cast iron for crucibles.

A simpler procedure is to use a conical crucible open at the bottom and placed on a steel plate. After ca. 2 h the crucible can be lifted from its bottom plate. The block is then pushed onto an inclined plane and onto a band conveyor which transports it to the crusher. Conveyor tapping systems, which allow continuous transport of the calcium carbide from the furnace to the crusher, have been developed [34].

All attempts to use even a part of the heat content of the calcium carbide block (ca. 33 % of the energy used in production) have failed.

5.2. Size Reduction

Because calcium carbide reacts with atmospheric water vapor, further processing of the block is started when its average temperature reaches ca. 400 °C, to minimize the losses of acetylene during processing. The method of processing depends on the intended use of the calcium carbide. The first step is always to crush the block, usually to < 100 mm. Then the desired size grading is produced by sieving, further crushing, and, if necessary, milling in impact mills. Magnetic impurities (iron and ferrosilicon) must be removed from the calcium carbide. For this purpose, magnetic separators are installed in all stages of the size reduction process.

5.3. Quality Specifications

In many countries the quality requirements are laid down in standard specifications:

United States	Federal Specification 0-6-101 a (July, 1949)
Australia	Standards Association of Australia, Publication No. K 49 (1931)
Belgium	Norme Belge, NBN 211-01 (01.72)
France	Norme Française, NF T 24-001 (10.54 + 09.55)
Germany	DIN 53922 (07.79)
United Kingdom	British Standard 642 (1965, 11.66)
India	Indian Standard IS 1040 (1978)
Israel	Israel Standard 267 T [250 × 4], SJ 446 (07.62)
Japan	Japanese Industrial Standard JIS K 1901 (1974)
Mexico	Norme Official K 23 (1945)

Normally these standards specify sieve analysis, dust content, gas generation, and phosphorus content.

The principal criterion of the quality of calcium carbide is the amount of acetylene produced per unit mass of calcium carbide by reaction with water – the so-called *liter number*, because it is a direct measure of the CaC_2 content of the carbide.

The method of determining this gas yield is laid down in the standard specifications. The British standard calculates the dry gas volume at atmospheric pressure and 15 °C, whereas the German standard assumes that the gas is saturated with water vapor at 15 °C. (Such differences explain the differences in the liter numbers.)

When calcium carbide is crushed, the impurities concentrate in the finer fractions, and thus the minimum liter number of commercial calcium carbide depends on the grain size. For the coarsest size fraction the British standard requires 295 L/kg, and the German standard 300 L/kg. For smaller size fractions, e.g., 4 – 7 mm, the British standard is 275 L/kg, and the German standard 260 L/kg.

Because the gas determination methods in all specifications are time-consuming, industry has developed methods of testing for liter number by using small amounts of calcium carbide in more compact apparatus. In this way a large number of tests of sufficient accuracy can be carried out in a short time, and calcium carbide producers can continuously monitor their production.

The most important *size ranges* specified in individual standards are (in mm): 2 – 4, 4 – 7, 7 – 15, 15 – 25, and 25 – 50. The British standard also gives the ranges 1 – 2, 4 – 80, 1 – 80, and 0 – 80. It also mentions the well-known commercial form 14 ND (0.4 – 1.7 mm), without making it a standard.

The phosphine content of the acetylene produced is specified in all the standards. The maximum is in the region of 0.1 vol %. Detailed methods for the determination of sulfur and of materials insoluble in dilute sulfuric acid are also given, but no upper limits are set.

For the determination of the quality of the granular calcium carbide, samples must be taken correctly. All standard specifications therefore give precise instructions regarding sampling and sample preparation.

5.4. Transport and Storage

Owing to the fact that calcium carbide produces a flammable gas in the presence of water, it is classed as a hazardous industrial material. Therefore, in most countries special regulations concerning packing and storage have been issued.

In Britain "The Storage of Carbide of Calcium", published by the British Acetylene Association, states the regulations.

According to the "Verordnung über Acetylenanlagen und Calciumcarbidlager", anyone in Germany who stores calcium carbide must register [35], [36]. The requirements for these storage sites are stated in "Technische Regeln für Acetylenanlagen und Calciumcarbidlager" (TRAC 301, 1982). In addition, the provisions of the "Arbeitsstoffverordnung" (industrial materials regulations) are applicable.

The following international regulations govern the transport of calcium carbide [37–39]:

Land transport (ADR/RID)
  Class 4.3
  Item 17b
  UN no. 1402
Sea transport (IMDG)
  Class 4.3
  UN no. 1402
  PG II
  MFAG 705
  EMS 4.3-03
Air transport (ICAO-TI, IATA-DGR)
  Class 4.3
  UN no. 1402
  PG II

Labelling (EU directives):

Calcium Carbide
EEC no. 200-848-3
Symbol: F – Highly Flammable
R phrases
  R15: Contact with water liberates extremely flammable gases
S phrases
  S8: keep container dry
  S43: In case of fire use dry sand. Never use water.

In general, steel containers are permitted for transport of calcium carbide, e.g., drums or kegs. Under certain conditions transport in cardboard cartons is allowed, provided that the carbide is also sealed in airtight bags.

For the transport of larger amounts of calcium carbide, containers with a capacity of 1 – 20 t have been introduced. Fine granular calcium carbide is also conveyed in tankers that can be discharged pneumatically. For storage and transport in the open, only suitably equipped containers are allowed, not drums or kegs.

6. Environmental Protection

The raw materials used in manufacturing calcium carbide are nonpoisonous and present no hazard to the environment. During production, transport, and preparation of these raw materials, dust can cause a nuisance in the vicinity of the factory and at the workplace and is therefore removed by air extraction and retained by means of filters.

Precautions, especially breathing protection, must be taken when handling hot Söderberg material. The carbide furnaces of the open construction emit lime and coke dust from the surface of the burden. As a rule, open furnaces are fitted with large extraction hoods so that these emissions, together with lime dust arising during tapping, can be extracted and filtered. Closed furnaces emit dust only on tapping. This dust, because of the extremely small particle size, makes high demands on the filtration equipment.

Carbon monoxide gas from open furnaces burns directly at the surface of the feed material to harmless carbon dioxide. From closed furnaces it is usually used as fuel gas. The traces of cyanide in the furnace gas are converted into harmless compounds by special treatment in the gas purification equipment. The residues from wet purification are usually dumped.

7. Uses

Calcium carbide has three main uses: the manufacture of acetylene (→ Acetylene, Chap. 4.3.4.), reaction with nitrogen to give cyanamide, see → Cyanamides, and the desulfurization of pig iron, cast iron, and steel. Since 1960 the use of carbide-based acetylene has declined worldwide as a raw material for heavy chemicals due to the widespread use of petrochemicals. Only a few chemical products are still produced from acetylene. These include butynediol, a component of plastics and fibers, and acetylene black, used in dry batteries.

Acetylene from calcium carbide still holds a firm position in the field of gas welding. The

acetylene cylinder, in spite of the rapid development of techniques of joining materials, is indispensable, especially in pipeline construction, on account of its adaptability and mobility.

Calcium carbide has an important application in metallurgy because it reacts with sulfur. The increasingly strict standards for steel have led to requirements for lower sulfur contents. The lowest sulfur contents can be achieved by desulfurizing the hot metal before the converter. Injection of calcium carbide into the melt was introduced in 1970 and is carried out in a transport ladle. Generally the sulfur content can be reduced from 0.2 % to 0.001 %. Since the reaction of calcium carbide with sulfur takes place on the surface of the solid carbide, the calcium carbide should be ground to $< 100\,\mu m$. Combinations of calcium carbide with magnesium are increasing in importance. A gas-evolving component is added to the desulfurization mixture to improve the reactivity of the calcium carbide in the hot metal [40], [41].

Consumption of calcium carbide for hot metal desulfurization in 1997 was: Europe 100 000 t/a; USA 15 000 t/a; India, Japan, and South Africa 30 000 t/a.

In foundry technology, coarse-grained calcium carbide is used in combination with additives such as fluorspar. The calcium carbide is stirred into the ladle after tapping and before casting.

8. Economic Aspects

Between 1962 and 1965 the world output of calcium carbide reached its maximum, nearly 10×10^6 t/a. Since then the decline has been steady. This decline has been accompanied by a shift of the main production centers.

Table 3 lists production for the years 1962, 1972, 1982, and 1990. In the 1960s and 1970s, there was a severe decline in North America, Western Europe, and Japan on account of conversion to petroleum-based products and reduced output of calcium cyanamide for fertilizer, whereas Eastern Europe showed an increase in calcium carbide production. In the 1980s, however, replacement of calcium carbide by petrochemical raw materials began in these countries, too. The rapid decline in calcium carbide production in the last few years has been due to the increasing availability of petroleum in many countries, including South Africa. Production in the former German Democratic Republic has ceased. In Central and South America small installations still take advantage of favorable local conditions. In Asia, especially China, calcium carbide production has increased in the last few decades.

Table 3. World calcium carbide production, 1000 t/a

Region	1962	1972	1982	1990
Western Europe	2540	1410	660	500
Eastern Europe	2200	3300	2600	1710
America	14 00	710	470	570
Asia and Africa	1860	2080	2670	2080
World production	*8000*	*7500*	*6400*	*4860*

The general trend of calcium carbide production will remain stagnant or in a slightly downward direction worldwide.

9. Toxicology

The toxicological dangers of technical-grade calcium carbide arise only as a result of impurities, which on reaction with water give rise to the formation of hydrides of phosphorus, etc. (→ Acetylene, Chap. 8.).

1. Introduction

Calcium chloride is found in small quantities, along with other salts, in seawater and in many mineral springs. It is found in higher concentrations in natural brines in California and Michigan (USA), in the mineral antarcticite [*29854-80-6*], $CaCl_2 \cdot 6\,H_2O$; in the yellowcolored mineral tachydrite [*12194-70-6*] (from the Greek word meaning easily soluble), $2\,MgCl_2 \cdot CaCl_2 \cdot 12\,H_2O$; and in the mineral chlorocalcite [*12418-72-3*], $KCaCl_3$. Calcium chloride is reportedly also contained in small amounts in the mineralcarnallite, [*63919-72-2*], $KMgCl_3$ [1–4].

Calcium chloride appears to have been discovered as early as the 15th century but apparently received little attention or study until the latter part of the 18th century. All of the work was done with laboratory prepared samples because it was not commercially produced until after the development of the Solvay ammonia–soda process in the mid-1800s. This process was originally designed to produce soda ash (crude sodium carbonate). Calcium chloride was considered a waste product until uses for it were developed some years later. Its importance has grown continuously to the extent that it is now invaluable for various uses, including ice and dust control, oil well drilling, refrigeration, coal thawing, and food processing. Natural brines account for as much as 70–75 % of United States calcium chloride production in 1983 [5], [6].

2. Physical Properties

Calcium chloride, $CaCl_2$, M_r 110.99, is a white, odorless, extremely water soluble salt that forms hydrates with properties as indicated in Table 1.

Figure 1. Solubility of pure calcium chloride in water–freezing point diagram (Courtesy Allied Corp.)
Data for areas A–J given in Table 2.

Calcium chloride is highly soluble in water over a wide temperature range, with maximum solubility of approximately 75 % at temperatures above 175 °C. Although calcium chloride dissolves readily in water to form highly concentrated solutions, due account must be taken of the

temperature at which solid hydrates precipitate from these solutions. A detailed diagram of the solid and liquid phases, showing temperatures and concentrations of calcium chloride and water, is given in Figure 1. The solubility data in this diagram were obtained with pure calcium chloride. The saturation curve and the freezing points of solutions of commercial calcium chloride up to a concentration of 29.8 % $CaCl_2$ are practically the same as for pure solutions; above 29.8 % $CaCl_2$, the curve follows the same general pattern (and direction) but falls slightly to the left of the curve for pure calcium chloride. The difference in the curves is small between 29.8 % and 50 % $CaCl_2$ but increases somewhat at higher concentrations.

The effect of a small percentage of sodium chloride (NaCl) and other minor impurities is to raise the saturation temperature slightly for any given concentration of calcium chloride. Thus, a 40 % $CaCl_2$ solution becomes saturated when cooled to ca. 13 °C, whereas a pure 40 % $CaCl_2$ solution is saturated at ca. 12 °C.

Calcium chloride forms solutions with high densities. This property is commonly used to determine the strength of calcium chloride brines. Density data for commercial calcium chloride solutions are presented in Table 3.

Calcium chloride is extremely hygroscopic and deliquescent when the vapor pressure of the air equals or exceeds that of the saturated solution at the prevailing temperature. Data on calcium chloride solutions in equilibrium with air at various temperatures and relative humidities are presented in Figure 2.

Figure 2. Vapor pressure of calcium chloride solutions (Courtesy Allied Corp.)

Freshly prepared solutions of commercial calcium chloride are somewhat alkaline due to the presence of a small amount of lime (CaO). Although these solutions may exhibit a relatively high pH (pH $\leqq$ 10.3), they have little acid-neutralizing value because of the small percentage of lime present.

Calcium chloride solutions exposed to air gradually absorb carbon dioxide to form calcium

3. Chemical Properties

Calcium chloride is a source of soluble inorganic calcium and reacts with carbonates, fluorides, and sulfates to form insoluble or moderately soluble salts. Calcium chloride forms water soluble compounds with ammonia, e.g., $CaCl_2 \cdot 8NH_3$, and with alcohol, e.g., $CaCl_2 \cdot C_2H_5OH$. Calcium chloride reacts with sodium tungstate [*13472-45-2*], Na_2WO_4, to form calcium tungstate [*7790-75-2*], $CaWO_4$, also known as synthetic scheelite [7–11].

4. Production

Calcium chloride is produced in commercial quantities by several processes: (1) refining of natural brines, (2) the reaction of calcium hydroxide with ammonium chloride in Solvay (synthetic) soda ash production, and (3) the reaction of hydrochloric acid with calcium carbonate. The refining of natural brines and calcium chloride recovered from synthetic soda ash production together account for over 90 % of calcium chloride production [6].

Natural brines in California and Michigan contain a mixture of chloride salts of calcium, magnesium, and sodium. Magnesium is removed by precipitating magnesium hydroxide, $Mg(OH)_2$, with lime. The solution remaining after filtration is concentrated. Sodium chloride precipitates because it is only slightly soluble in calcium chloride solutions.

In the *ammonia – soda* (Solvay) *process,* ammonia [*7664-41-7*] serves as a catalystfor the

reaction of sodium chloride [*7647-14-5*] with calciumcarbonate [*471-34-1*] (→ Sodium Carbonates). Although this process is actually quite complicated, it can besummarized as follows:

$$2\,NaCl + CaCO_3 \xrightarrow{NH_3} Na_2CO_3 + CaCl_2$$

The calcium chloride solutions produced by the purification of natural brines and by the Solvay process are relatively dilute. Part of the solution is concentrated by evaporation to 30 – 45 % calcium chloride and marketed as such. An additional part is concentrated to ca. 75 % solids, corresponding to calcium chloride dihydrate, $CaCl_2 \cdot 2\,H_2O$. This material is flaked and dried to the commercial calcium chloride dihydrate (77 – 82 % $CaCl_2$) and anhydrous (94 – 97 % $CaCl_2$) products [12–14]. Anhydrous pellets can be produced by substituting an agglomeration procedure in place of the flaker [15], [16].

5. Environmental Protection

Calcium chloride is not generally considered harmful to the environment. However, as with any chemical, calcium chloride spills should be promptly contained and disposed of in accordance with local ordinances.

The taste threshold of calcium chloride in potable water is reported as 150 – 350 ppm. However, depending on the calcium hardness of the water, even concentrations as low as 50 ppm can be objectionable [17].

In high concentrations (>1 000 ppm), calcium chloride retards plant growth and can damage foliage. Because calcium is a nutrient for plants, these effects are most likely caused by accumulation of the chloride ion in the plant tissue. High chloride concentrations are seldom found in U.S. water supplies, even in areas of high salt usage for dust and ice control [17–19].

Calcium chloride concentrations of 10 000 to 20 000 ppm in water have been shown to be hazardous to animals and fish because of differences in osmotic pressure. The effects vary from reduced growth rate and impaired reproduction to death. Such high concentrations are readily detected by the presence of an unpleasant saline taste. In general, the environmental effects of calcium chloride are quite similar to those of rock salt (sodium chloride) [17], [20].

6. Quality Specifications

The major uses of calcium chloride (ice and dust control) do not require high chemical purity. However, the calcium chloride must be free of materials that are harmful to the environment. Commercial calcium chloride from the three main processes contains low levels of heavy metals and organic compounds and is relatively innocuous.

Standard grades of calcium chloride are listed in Table 4 [21–23].

Total alkali chlorides are generally the impurities of concern to calcium chloride producers. These impurities, essentially sodium chloride with smaller amounts of potassium chloride, are known to be harmful when included in cement. Because calcium chloride is utilized in cement, its total alkali chlorides content must be kept at a reasonable level.

In general, commercial calcium chloride meets the requirements of the Food Chemicals Codex. Because of the high quality of commercial calcium chloride, the FDA has granted variances covering some commercial grades of calcium chloride for use in vegetable brining and apple dipping. However, direct addition of commercial grades of calcium chloride to foods, such as cheese, continues to require food-grade material.

7. Chemical Analysis

Routine analytical tests performed on calcium chloride include: assay, total alkali chlorides, percent sodium chloride, percent potassium chloride, and various granulation tests [24–27].

The *concentration* of calcium chloride is most easily determined by an ethylenediaminetetraacetic acid (EDTA) titration. This procedure determines total calcium, which is expressed as calcium chloride. In the determination of total alkali chlorides, sodium chloride, and potassium chloride, atomic absorption spectroscopy is most widely used. Sodium and potassium are determined individually, and these results are combined and expressed as total alkali chlorides.

Table 4. Calcium chloride standards

	ASTM [a] D 98-80			AASHTO [b] M 144-78		Food Chemicals Codex [c]	
	77 %	90 %	94 %	77 %	94 %	77 %	94 %
Calcium chloride, % min.	77	90	94	77	94	74.7 to 80.8	93

Fluoride, % max. as F	–	–	–	–	–	0.004	0.004
Heavy metals, % max. as Pb	–	–	–	–	–	0.002	0.002
Lead, ppm max. as Pb	–	–	–	–	–	10	10

[a] American Society of Testing Materials specification is based on 90.5 % calcium chloride; for comparison, the values shown have been adjusted and are on an "as received" basis.
[b] American Association of State Highway & Transportation Officials.
[c] Food Chemicals Codex actually specifies a range of 99 – 107 % for calcium chloride dihydrate assay; for comparison, this range has been converted to actual calcium chloride content

8. Storage and Transportation

Calcium chloride is not classified as a hazardous material by the DOT and is, therefore, not subject to specific handling regulations [28]. The various modes of transportation include: bulk rail cars (30 – 90 t), bulk trucks (up to 20 t), box rail cars, and van and flatbed trailers. Depending on whether the shipments are in liquid or dry form, there are several variations to the above general classifications.

Dry bulk calcium chloride can be stored in bins fabricated from most construction-grade steel materials. Care should be taken to minimize moisture. Venting should be limited to times of filling and discharging calcium chloride from the storage bin. Liquid calcium chloride can be stored in either horizontal or vertical cylindrical tanks constructed of steel. Fiberglass and plastic may also be used within limits of strength and temperature.

Because calcium chloride is hygroscopic, the common safety precautions involved in the handling of chemicals should be observed: wearing gloves, boots, long-sleeve shirts, and safety glasses, and if dry products are being handled, dust protection must be insured.

9. Uses

Calcium chloride's versatility is related to its unique combination of physical properties: moisture attraction and retention, high solubility, high heat of solution, and freezing point depression of solutions. Calcium chloride is most widely known for its deicing and dust-controlling abilities.

The largest market for calcium chloride (30 % of total production) is for *deicing* of roads, sidewalks, and parking lots (see Table 5). Calcium chloride melts ice at temperatures as low as −51 °C (−60 °F). Because it liberates heat when exposed to moisture, ice is melted quickly, usually within 15 – 30 min of application. Calcium chloride is also used in conjunction with rock salt (sodium chloride) to enhance and sustain the effectiveness of the rock salt.

Table 5. Calcium chloride end uses in the United States

	%
Deicing	30
Dust control, road stabilization	25
Industrial (refrigerant, coal thawing, etc.)	15
Oil and gas drilling fluids	10
Concrete	5
Tire ballast	4
Miscellaneous	11

Dust control accounts for ca. 25 % of calcium chloride production. Its hygroscopic and deliquescent properties make it ideal for this use. Calcium chloride absorbs moisture from the air and forms a solution that acts to coat dust particles and bind them together, greatly reducing dusting. Calcium chloride solutions are slow to evaporate because of their low vapor pressure

and are, therefore, useful in the compaction of road surfaces.

Calcium chloride is used in the *cement* and *concrete* industries (→ Cement and Concrete). Addition of 1 – 2 % calcium chloride accelerates the setting time of concrete, resulting in earlier strength development. Calcium chloride should not be considered as an antifreeze in concreting; however, the addition of calcium chloride to concrete mixes poured at temperatures below 21 °C (70 °F) largely offsets the retarding effects of the lower temperatures [29].

Calcium chloride solutions, because of their low freezing points, are used extensively as heat-transfer media in *food processing* (→ Foods, 2. Food Technology). Calcium chloride brine greatly increases the heat-transfer rate compared to chilled air or to a sodium chloride brine. Contact time between the brine and the various food molds is decreased, resulting in higher production rates [30].

Calcium chloride is also used in the food industry to increase the firmness of fruits and vegetables and to prevent spoilage during processing.

In the *petroleum* and *petrochemical industries* calcium chloride is used as a desiccant for hydrocarbons. It is also used in drilling fluids, packer fluids, completion fluids, and workover fluids in oil well drilling.

Other uses for calcium chloride include:

Adhesives	– humectant – lowers gel temperature
Animal feed supplement	– source of calcium
Tractor tire weight	– lowers freezing temperature of water – improves traction by increasing tire weight
Highway shoulder and base stabilization	– retains moisture which im proves compaction of soils
Freezeproofing of coal	– lowers freezing point of residual water
Paper manufacture	– increases web strength of corrugated media
Rubber manufacture	– coagulates latex emulsions
Steel and pig iron manufacture	– eliminates alkalies that attack furnace refractory
Wastewater treatment	– precipitates fluorides – breaks oil emulsions – densifies floc

10. Economic Aspects

The majority of the world's calcium chloride is a byproduct from synthetic (Solvay) soda ash production. About 1 t of calcium chloride (anhydrous basis) is produced with each ton of synthetic soda ash. Synthetic soda ash production worldwide was ca. 20.8×10^6 t in 1979, and $31{,}5 \cdot 10^6$ t in 1993. A similar quantity of calcium chloride was also produced. However, most of this material is produced as a 5 – 10 % waste solution and is simply discarded. World production of calcium chloride (waste and refined) from the Solvay process is shown by continent in Table 6 [31].

Table 6. World calcium chloride production from the Solvay process (1979)

Continent	Production (100 % basis), 10^3 t
Europe *	15 480
Asia	3 390
North America	1 460
Australia	290
South America	210
Africa	10
Total	20 840

* Includes the USSR

In the United States, synthetic soda ash has been largely replaced by natural material from Sweetwater County, Wyoming. As a result, natural brines now account for ca. 70 % of the U.S. calcium chloride production. The major calcium chloride producers and their capacities are shown in Table 7.

Table 7. United States calcium chloride producers (1983)

Producer	Capacity (100 % basis), $\times 10^3$ t
Allied	263
Dow	900
Hill Brothers	4
Leslie Salt	27
National Chloride	13
Occidental	6
Reichhold	6
Texas United	32
Wilkinson Salt	15
Total	1266

Because of the widespread use of calcium chloride in deicing and dust control, demand for this chemical is erratic (demand, 100 % basis, 1000 t):

Year	1975	1979	1980	1981	1982
Demand	550	690	550	670	590

Demand is expected to grow at a rate of 3 % per year through 1986 [6], [32].

11. Toxicology and Occupational Health

Calcium chloride is not generally considered toxic; however, prolonged exposure may be detrimental to health. Contact with skin may cause irritation. Calcium chloride can irritate or burn eyes. Inhalation of product dust may irritate nose, throat, or lungs. Ingestion could irritate the mouth, esophagus, or stomach. In rats calcium chloride has an acute oral LD_{50} of 1 g/kg. No TLV or MAK has been established for calcium chloride in air [33].

1. Introduction

Both gypsum [*13397-24-5*], $CaSO_4 \cdot 2\,H_2O$ [*10101-41-4*], and anhydrite [*14798-04-0*], $CaSO_4$ [*7778-18-9*], are widely distributed in the earth's crust. Only in volcanic regions are gypsum and anhydrite rock completely absent. In addition, large quantities of gypsum and anhydrite are obtained from industrial processes when flue gases are desulfurized or calcium salts are reacted with sulfuric acid. In these cases calcium sulfate is usually obtained as a moist, fine powder.

Gypsum is useful as an industrial material because (1) it readily loses its water of hydration when heated, producing partially or totally dehydrated calcined gypsum, and (2) when water is added to this calcined gypsum, it reverts to the original dihydrate – the set and hardened gypsum product. These two phenomena, dehydration and rehydration, are the basis of gypsum technology:

Dehydration

$$CaSO_4 \cdot 2\,H_2O + \text{heat} \longrightarrow CaSO_4 \cdot 1/2\,H_2O + 3/2\,H_2O$$

$$CaSO_4 \cdot 2\,H_2O + \text{heat} \longrightarrow CaSO_4 + 2\,H_2O$$

Rehydration

$$CaSO_4 \cdot 1/2\,H_2O + 3/2\,H_2O \longrightarrow CaSO_4 \cdot 2\,H_2O + \text{heat}$$

$$CaSO_4 + 2\,H_2O \longrightarrow CaSO_4 \cdot 2\,H_2O + \text{heat}$$

The apparent density of the rehydrated calcium sulfate is much lower, 500 – 1500 kg/m^3, than the density of the calcium sulfate rock, 2300 kg/m^3.

Gypsum and anhydrite are nontoxic.

Both gypsum plaster and lime were used as mortar in antiquity. Gypsum was called *gatch* in Persian, *gypsos* in Greek, and *gypsum* in Latin. The Iranians, Egyptians, Babylonians, Greeks, and Romans were familiar with the art of working with gypsum plaster, examples being the

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a04_555

walls of Jericho, the pyramid of Cheops, the palace of Knossos, and the decorated interior walls of Pompeii. In Germany gypsum plaster was used as mortar in walls and buildings during the early Middle ages, e.g., the monastery at Walkenried in the Harz Mountains. It gained popularity tremendously, reaching its peak during the Baroque and Rococo periods. Examples are the Wessobrunn school for stucco workers [17] and the stucco decorations in Charlottenburg palace, Berlin. The expansion of the cement industry in the second half of the nineteenth century also considerably increased the use of gypsum.

Over the centuries the gypsum industry has developed empirically out of the old craft of gypsum plastering. The distinctions between gypsum plaster and lime, however, remained obscure up to the eighteenth century. Research into the principles of gypsum technology was begun in 1765 by LAVOISIER, and has continued to this day. However, a craft so firmly steeped in tradition was slow to accept scientific conclusions, and only in the last few decades has gypsum manufacture developed into a modern industry [1].

2. The $CaSO_4 - H_2O$ System

2.1. Phases

The $CaSO_4 - H_2O$ system is characterized by five solid phases. Four exist at room temperature: calcium sulfate dihydrate, calcium sulfate hemihydrate, anhydrite III, and anhydrite II. The fifth phase, anhydrite I, only exists above 1180 °C [19], and it has not proved possible to produce a stable form of anhydrite I below that temperature. Table 1 characterizes the phases in the $CaSO_4 - H_2O$ system. The first four phases are of interest to industry.

Calcium sulfate dihydrate, $CaSO_4 \cdot 2\,H_2O$, is both the starting material before dehydration and the final product after rehydration. Calcium sulfate hemihydrate [*10034-76-1*], $CaSO_4 \cdot 1/2\,H_2O$, occurs in two different forms, α and β, representing two limiting states [20]. They differ from each other in their application characteristics, their heats of hydration, and their methods of preparation (see Table 8) [21]. The α-hemihydrate (Fig. 1) consists of compact, well-formed, transparent, large primary particles. The β-hemihydrate (Fig. 2) forms flaky, rugged secondary particles made up of extremely small crystals.

Figure 1. α-Hemihydrate (scanning electron micrograph) 200×

Figure 2. β-Hemihydrate (scanning electron micrograph) 200×

LEHMANN et al. [22] postulated three limiting stages for anhydrite III, also known as soluble anhydrite: β-anhydrite III, β-anhydrite III$'$, and α-anhydrite III. The three stages of anhydrite III were characterized by X-ray analysis, differential thermal analysis, scanning electron microscopy, mercury porosimetry, and measurement of the specific surface area. Anhydrite II is the naturally occurring form and also that

produced from calcining the dihydrate, hemihydrate, and anhydrite III at elevated temperature.

The most important physical properties of the calcium sulfate phases are shown in Table 2.

2.2. Laboratory Synthesis

The thermodynamic stability ranges for the calcium sulfate phases are shown in Table 1. Below 40 °C, i.e., under normal atmospheric conditions, only calcium sulfate dihydrate is stable. The other phases are obtained at higher temperatures by progressive dehydration of the calcium dihydrate in the following order:

dihydrate → hemihydrate → anhydrite III → anhydrite II

Under normal atmospheric conditions hemihydrate and anhydrite III are metastable, and below 40 °C in the presence of water or water vapor they undergo conversion to the dihydrate, as anhydrite II does. However, between 40 °C and 1180 °C anhydrite II is stable.

To synthesize pure phases in the laboratory, β-hemihydrate is made from the dihydrate by heating at a low water-vapor partial pressure, i.e., in dry air or vacuum, between 45 °C and 200 °C. Further careful heating at 50 °C in a vacuum or up to ca. 200 °C at atmospheric pressure produces β-anhydrite III.

At very low water-vapor partial pressure, if water vapor is released rapidly and particle size is small, β-anhydrite III′ forms directly from the dihydrate, without formation of an intermediate hemihydrate. The specific surface area of such β-anhydrite III′ can be up to ten times that of β-anhydrite III.

α-Hemihydrate is obtained from the dihydrate at high water-vapor partial pressure, e.g., above 45 °C in acid or salt solutions, or above 97.2 °C in water under pressure (e.g., 134 °C, 3 bar, 4 h). Further careful release of water at 50 °C in a vacuum or at 100 °C under atmospheric pressure yields α-anhydrite III.

Anhydrite III is difficult to prepare pure because anhydrite II begins to form above 100 °C, and anhydrite III reacts readily with water vapor to form hemihydrate.

The β-hemihydrates from β-anhydrite III and β-anhydrite III′ differ in their physical properties [23]. Therefore, hemihydrates from β-anhydrite III′ should be designated as β-hemihydrate′. α-Anhydrite III absorbs water vapor to form α-hemihydrate. Likewise, the hemihydrates, in humid air, reversibly adsorb up to 2 % of their weight in water without converting to dihydrate. This nonstoichiometric water in the hemihydrate can be completely removed by drying at 40 °C.

Gypsum dehydration kinetics have been investigated by several authors. Neutron and X-ray powder diffraction studies have shown that the dehydration (and hydration) mechanism is strongly topotactic in the temperature range of 20 – 350 °C [24], [25]. In neutron thermodiffractometry experiments it was found that gypsum decomposes to $CaSO_4(H_2O)_{0.5}$, then to anhydrite III, and finally to anhydrite II. With high local steam pressure, a subhydrate with 0.74 H_2O was found [25]. According to another paper three phases of the α-hemihydrate type can be prepared as pure samples: $CaSO_4(H_2O)_{0.6}$, $CaSO_4(H_2O)_{0.5}$, and anhydrite III. The crystal structures of these phases were determined; data for $CaSO_4(H_2O)_{0.5}$ and for anhydrite III are listed in Table 2. The structure of the subhydrate $CaSO_4(H_2O)_{0.6}$ was found to be monoclinic, space group $I121$, with a = 1.19845, b = 0.69292, c = 1.27505 nm and β = 90 °. The density is 2.74 g/cm^3 [26]. In general the hemihydrate $CaSO_4(H_2O)_{0.5}$ is considered to be the kinetically most stable subhydrate. Table 2 also lists the well-established crystallographic data of gypsum [27] and of anhydrite II [28], [29].

Anhydrite II is formed at temperatures between 200 °C and 1180 °C. Above 1180 °C, anhydrite I forms; below 1180 °C it reverts to anhydrite II.

Another mechanism for conversion of gypsum directly to anhydrite II has been found in the catalytic action of small quantities of sulfuric acid on moist, finely divided gypsum at 100 – 200 °C. In this case anhydrite II with orthorhombic crystal structure is produced by neoformation [30].

2.3. Industrial Dehydration of Gypsum

Industrially it is most important that dehydration is achieved in the shortest time with the lowest energy consumption, i.e., that the costs be held to a minimum. Because of kinetic inhibitions calcination is carried out at much higher

temperatures than those used in the laboratory (Table 1). Rarely are pure phases produced during manufacture; rather, mixtures of phases of the $CaSO_4 - H_2O$ system are produced. Three types of calcined anhydrite II (anhydrous gypsum plaster or overburnt plaster) are manufactured, depending on burn temperature and time:

1) Anhydrite II-s (slowly soluble anhydrite), produced between 300 and 500 °C
2) Anhydrite II-u (insoluble anhydrite), produced between 500 and 700 °C
3) Anhydrite II-E (partially dissociated anhydrite; floor plaster, *Estrichgips*), produced above ca. 700 °C

In use the difference among these products lies in the rates of rehydration with water, which for anhydrite II-s is fast, for anhydrite II-u slow, and for anhydrite II-E in between, a little faster than anhydrite II-u (see Fig. 8). Transitions between these different stages of reaction are possible.

Anhydrite II-E consists of a solid mixture of anhydrite II and calcium oxide formed by the partial dissociation of anhydrite into sulfur trioxide and calcium oxide when raw gypsum is heated above 700 °C. The presence of impurities lowers the normal dissociation temperature of anhydrite II, ca. 1450 °C.

2.4. Energy Aspects

KELLY et al. made a thorough study of the thermodynamic properties of the $CaSO_4 - H_2O$ system [31], [32]. Tables 3 and 4 list the heats of hydration and dehydration of the various phase changes that are of industrial significance.

2.5. Structure, Mixed Compounds, Solubility

Crystal Structure. All structures in the $CaSO_4 - H_2O$ system consist of chains of alternate Ca^{2+} and SO_4^{2-} ions. These $CaSO_4$ chains remain intact during phase changes. Calcium sulfate dihydrate has a layered structure, and the water of crystallization is embedded between the layers. When calcium sulfate dihydrate is dehydrated to hemihydrate, a tunnel structure is formed with wide channels parallel to the $CaSO_4$ chains. In the subhydrates the tunnels are filled with water molecules; in anhydrite III they are empty. The relative ease of escape of these water molecules explains the facile conversion from subhydrate to anhydrite III. Anhydrite II exhibits closest packing of ions, which makes it the densest and strongest of the calcium sulfates. However, lacking empty channels, it reacts only very slowly with water. The α- and β-forms of calcium sulfate hemihydrate exhibit no crystallographic differences. The β-forms of calcium sulfate hemihydrate are active states of the α-form [33].

Isomorphism. Isomorphic incorporation of chemical compounds into the lattice of $CaSO_4 - H_2O$ phases is of interest in connection with FGD gypsums and phosphogypsums. Isomorphic incorporation of calcium hydrogenphosphate dihydrate occurs because $CaHPO_4 \cdot 2\,H_2O$ has lattice spacings almost identical with those of $CaSO_4 \cdot 2\,H_2O$ [34]. Monosodium phosphate, NaH_2PO_4, can also be incorporated into the gypsum lattice [35]. KITCHEN et al. [36] consider isomorphism between the ions AlF_5^{2-} and SO_4^{2-} a possibility. EIPELTAUER [20], [37] reports on further isomorphism, incorporation of the anion FPO_3^{2-} as well as the incorporation of Na^+, up to 0.2 % in the hemihydrate lattice, but only 0.02 % in the dihydrate lattice. Chlorides are not incorporated.

Double and Triple Salts. Gypsum forms double salts with alkali-metal and ammonium sulfates, some of which occur in nature, such as syngenite, $CaSO_4 \cdot K_2SO_4 \cdot H_2O$.

There are triple sulfates of calcium with the divalent ions of the iron and zinc subgroups and of manganese, copper, and magnesium along with the univalent alkali metals, also including ammonium. An example is the well-known polyhalite, $2\,CaSO_4 \cdot MgSO_4 \cdot K_2SO_4 \cdot 2\,H_2O$, which also occurs in natural salt deposits.

Ettringite, $3\,CaO \cdot Al_2O_3 \cdot 3\,CaSO_4 \cdot 32\,H_2O$, is important in cement chemistry [38], as are syngenite [39] and thaumasite [40].

Adducts. Gypsum forms sulfuric acid adducts in concentrated sulfuric acid: $CaSO_4 \cdot 3\,H_2SO_4$ and $CaSO_4 \cdot H_2SO_4$ [41].

Table 3. Heat of hydration

Phase change		Heat of hydration per mole (gram) of dihydrate at 25 °C, J
β-$CaSO_4 \cdot 1/2\,H_2O + 3/2\,H_2O$ (l)	$\longrightarrow CaSO_4 \cdot 2\,H_2O$	$19\,300 \pm 85$ (111.9 ± 0.50)
α-$CaSO_4 \cdot 1/2\,H_2O + 3/2\,H_2O$ (l)	$\longrightarrow CaSO_4 \cdot 2\,H_2O$	$17\,200 \pm 85$ (100.00 ± 0.50)
β-$CaSO_4$III $+ 2\,H_2O$ (l)	$\longrightarrow CaSO_4 \cdot 2\,H_2O$	$30\,200 \pm 85$ (175.3 ± 0.50)
α-$CaSO_4$III $+ 2\,H_2O$ (l)	$\longrightarrow CaSO_4 \cdot 2\,H_2O$	$25\,700 \pm 85$ (149.6 ± 0.50)
$CaSO_4$II $+ 2\,H_2O$ (l)	$\longrightarrow CaSO_4 \cdot 2\,H_2O$	$16\,900 \pm 85$ (98.0 ± 0.50)

Table 4. Heat of dehydration

Phase change	Heat of dehydration per mole or tonne of dehydration products at 25 °C	
	J/mol	kJ/t
$CaSO_4 \cdot 2\,H_2O \longrightarrow \beta$-$CaSO_4 \cdot 1/2\,H_2O + 3/2\,H_2O$ (g)	86 700	597 200
$CaSO_4 \cdot 2\,H_2O \longrightarrow \alpha$-$CaSO_4 \cdot 1/2\,H_2O + 3/2\,H_2O$ (g)	84 600	582 700
$CaSO_4 \cdot 2\,H_2O \longrightarrow \beta$-$CaSO_4$III $+ 2\,H_2O$ (g)	121 800	895 700
$CaSO_4 \cdot 2\,H_2O \longrightarrow \alpha$-$CaSO_4$III $+ 2\,H_2O$ (g)	117 400	863 100
$CaSO_4 \cdot 2\,H_2O \longrightarrow CaSO_4$II $+ 2\,H_2O$ (g)	108 600	798 000

Calcium sulfate dihydrate can combine with four molecules of urea to form an addition compound.

Solubility and Supersaturation. Gypsum is slightly soluble in water (see Table 2). The solubilities of the various forms of calcium sulfate are strongly affected by the presence of other solutes. The references [4], [7] can be consulted for particulars on the solubility of gypsum in acids, especially sulfuric acid, phosphoric acid, and nitric acid. Gypsum is readily soluble in glycerol and sugar solutions and in aqueous solutions of chelating agents, such as EDTA. All calcium sulfates have a tendency to supersaturation [4].

3. Occurrence, Raw Materials

3.1. Gypsum and Anhydrite Rock

Gypsum and anhydrite deposits are found in many countries. They originated from supersaturated aqueous solutions in shallow seas, which evaporated and deposited first carbonates, then sulfates, and finally chlorides, i.e., in order of increasing solubility [5], [6].

Gypsum and anhydrite are almost always found in the Permian, Triassic, and Tertiary formations. The Permian includes the Upper Permian (Zechstein deposits, Germany). The Triassic consists of Lower (*Buntsandstein*), Middle (*Muschelkalk*), and Upper Triassic (*Keuper*). The Tertiary deposits include the Eocene (Spain, Persia, Near East), the Oligocene (Paris), and the Miocene deposits (Mediterranean area, North africa). The Jurassic and Cretaceous formations, which lie between the Triassic and Tertiary, are almost devoid of useful gypsum deposits, as are the older pre-Permian formations – at least in the Old World – as, for example, the Carboniferous formation.

The accepted view is that gypsum, $CaSO_4 \cdot 2\,H_2O$, was formed upon initial crystallization. The best known deposits of primary gypsum are those of the Paris Basin and the areas around the Mediterranean. Under increased pressure and thus temperature, anhydrite could have developed locally from the original gypsum [42], [43]. However, uptake of surface water can convert the anhydrite back into gypsum. This gypsum is therefore a secondary rock, especially in formations older than the Middle Tertiary [44].

The various gypsum and anhydrite deposits differ in purity, structure, and color. The major impurities are calcium carbonate (limestone), dolomite, marl, clay; less frequently, silica, bitumen, glauberite, syngenite, and polyhalite.

Table 5. Chemical composition of some calcium sulfates

1) Zechstein gypsum; 2) Keuper gypsum; 3) Zechstein anhydrite; 4) Keuper anhydrite; 5) From Moroccan raw phosphate, dihydrate process; 6) From Kola raw phosphate, dihydrate/hemihydrate process, after rehydration to dihydrate; 7) From Moroccan raw phosphate, hemihydrate/dihydrate process; 8) From hydrofluoric acid production.

If these are present in the gypsum and anhydrite from its formation, they are called *primary impurities*. A distinction is drawn between carbonate – sulfate deposits, mainly found in the Upper Permian (Zechstein), and the clay – sulfate deposits, which predominate in the Triassic [45]. *Secondary impurities* are formed during exposure to materials flushed into cracks and leached cavities, but may also be introduced into the rock as waste material during mining. Gypsum is readily soluble in water, even if it is only slightly soluble, and therefore gypsum rock is leached by surface water. The chemical composition of some calcium sulfates is shown in Table 5.

Workable gypsum and anhydrite rock are structurally quite distinct from one another. The most important types of native gypsum are sparry gypsum, also called gypsum spar or flaky gypsum (selenite), fibrous gypsum, alabaster (grainy gypsum), gypsum rock (common gypsum, also massive gypsum), porphyritic gypsum, earthy gypsum (gypsite in the United States), and gypsum sand (contaminated with Glauber's salt $Na_2SO_4 \cdot 10H_2O$). Anhydrite, always crystalline, can either be sparry (anhydrite spar), coarse to close grained, or even rod shaped.

Gypsum can be pure white. If it contains iron oxide, it is reddish to yellowish. If clay and/or bitumen is present, it is gray to black. Very pure anhydrite is bluish white, but usually it is gray with a bluish tinge. The white veins sometimes found on the boundary between gypsum and anhydrite consist largely of glauberite ($CaSO_4 \cdot Na_2SO_4$) or Glauber's salt ($Na_2SO_4 \cdot 10H_2O$).

3.2. Flue Gas Desulfurization (FGD) Gypsum

FGD gypsum is produced from the desulfurization of combustion gases of fossil fuels (coal, lignite, oil) in power stations as a product with a specification and quality standards. The internationally accepted definition of FGD gypsum is: "Gypsum from flue gas desulfurization plants (FGD gypsum, desulfogypsum) is moist, finely

divided, crystalline, high-purity calcium sulfate dihydrate, $CaSO_4 \cdot 2\,H_2O$. It is specifically produced in a flue gas desulfurization process incorporating after lime(stone) scrubbing, a refining process involving oxidation followed by gypsum separation, washing, and dewatering" [46]. FGD gypsum is produced in four stages:

1) Desulfurization: In a first circuit the dedusted flue gas is sprayed with a limestone suspension in counterflow. The reaction, which takes place at pH 7 – 8, produces insoluble calcium sulfite:

$$SO_2\ (g) + CaCO_3\ (s) + 1/2\,H_2O \longrightarrow CaSO_3 \cdot 1/2\,H_2O\ (s) + CO_2\ (g)$$

The following stages (2 – 4) are recovery operations in which the FGD gypsum is formed and isolated.

2) Forced oxidation: In a second circuit the calcium sulfite reacts spontaneously with atmospheric oxygen at pH 5, initially forming soluble calcium bisulfite, which is then oxidized to calcium sulfate dihydrate:

$$CaSO_3 \cdot 1/2\,H_2O\ (s) + O_2\ (g) + 3\,H_2O \longrightarrow 2CaSO_4 \cdot 2\,H_2O\ (s)$$

During this procedure the gypsum crystals grow by continuous circulation to the required average size of 30 – 70 µm.

3) Gypsum separation: In a hydrocyclone, the calcium sulfate dihydrate crystals produced in the quencher slurry are separated and solid impurities are removed.

4) Gypsum washing and dewatering: The calcium sulfate crystals are separated from the process water in filters or centrifuges and washed with clean wash water to remove unwanted water-soluble chlorides and sodium and magnesium salts.

The resulting FGD gypsum contains < 10 wt % free moisture. About 5.4 t of gypsum is produced per tonne of sulfur in the fuel. Figure 3 shows a typical flow diagram of a flue gas desulfurization plant for producing FGD gypsum.

Sometimes FGD gypsum from lignite-fired power stations is darker than that from coal-fired power stations. Therefore a special "overflow cleaning" operation was developed to improve the color of lignite FGD gypsum. Such lignite FGD gypsum meets international quality specifications and can be used for all applications. This could be important, for example in Germany, where lignite FGD gypsum will predominate in the future [47]. A large-scale investigation has been carried out to compare FGD gypsum to natural gypsum in the production, processing, utilization, and disposal of building materials. The conclusion was that the differences in chemical composition and in trace element content between FGD gypsum and natural gypsum are insignificant. FGD gypsum can be used for the production of all building materials [48].

Table 6 lists quality standards for FGD gypsum.

Table 6. Quality standards for FGD gypsum

Quality parameters	Quality standards
Free moisture, wt %	< 10.0
Calcium sulfate dihydrate, wt %	> 95.0*
Magnesium oxide, water soluble, wt %	< 0.10
Sodium oxide, water soluble, wt %	< 0.06
Chloride, wt %	< 0.01
Sulfur dioxide, wt %	< 0.25
pH value	5 – 9
Color	white**
Odor	neutral
Toxicity	nontoxic

*The reduction of the calcium sulfate dihydrate content by inert elements is not detrimental to the different areas of application.
**Different color values may apply depending on the use of the FGD gypsum and the final products.

FGD gypsum is classified as a product and not as a waste, and it is therefore not included in the European Waste Catalogue (EWC). Furthermore, FGD gypsum is not included in the OECD lists for the Control of Transfrontier Movements of Wastes Destined for Recovery Operations. The EU customs code of FGD gypsum is 2520 20 90. The PRODCOM code of FGD gypsum in the international classification of goods for the production statistics of the EU Member States is 2653 10 003. FGD gypsum is used directly in the gypsum industry (and small quantities in the cement industry) without any further treatment, and is equivalent to natural gypsum.

The predicted quantities of FGD gypsum from coal-fired and lignite-fired power stations in Europe, the United States and Canada, and Japan and Taiwan in 1996 are listed in Table 7 [47].

Figure 3. Flow sheet of a flue gas desulfurization plant for producing FGD gypsum with the four operation stages 1 to 4 (see text for explanation) a) Quencher; b) Hydrocyclone; c) Filter

Table 7. Predicted quantities of FGD gypsum in 1996

Country	Quantity, 10^3 t
Germany	4 920
Denmark	340
Finland	190
United Kingdom	1 200
Italy	40
Netherlands	360
Austria	100
Poland	770
Russia	60
Czech Replublic	40
Ukraine	85
Total for Europe	8 225
USA and Canada	3 000
Japan and Taiwan	2 300

In Germany the quantities of FGD gypsum will rise from 4.9×10^6 t in 1996 to 6.3×10^6 t in the year 2000 due to lignite FGD gypsum from new power stations in the former Democratic Republic. In Spain, France, Italy and Turkey, fairly large quantities are to be expected after 1996. The quantities of FGD gypsum produced in Japan and Taiwan of ca. 2.3×10^6 t are expected to remain stable after 1996 [85]. The quantities of FGD gypsum predicted for the United States and Canada will probably be attained later than predicted above, i.e., only after 1996 [49].

3.3. Phosphogypsum

By far the largest amount of byproduct gypsum is obtained from the production of wet phosphoric acid from phosphate rock (usually fluorapatite) and sulfuric acid (see → Phosphoric Acid and Phosphates, Chap. 1.2.2.)

$$\underset{(504)}{Ca_5(PO_4)_3F} + \underset{(5\times98)}{5\,H_2SO_4} + \underset{(10\times18)}{10\,H_2O} \longrightarrow \underset{(5\times172)}{5\,CaSO_4\cdot 2\,H_2O} + \underset{(3\times98)}{3\,H_3PO_4} + \underset{(20)}{HF}$$

Worldwide, about 100×10^6 t/a of phosphogypsum is currently obtained. Phosphogypsum is a waste and therefore listed in the EWC as follows [51]:

06 00 00:	wastes from inorganic chemical processes
06 09 01:	phosphogypsum

In the OECD lists for the Control of Transfrontier Movements of Wastes, phosphogypsum is listed as follows [52]:

Amber List AB 140:	gypsum arising from chemical industry processes

This phosphogypsum is a moist, fine powder with a free water content of ca. 20 – 30 % and considerable amounts of impurities, the exact impurities and their amounts depending on the rock and the specific process. The radioactive substances present in small amounts in sedi-

mentary phosphate rock are partly transferred to the phosphogypsum as ^{226}Ra, leading to slightly increased radioactivity of such gypsums [14]. About 1.7 t of gypsum is obtained per tonne of raw phosphate, corresponding to 5 t of gypsum per tonne of phosphorus pentoxide produced.

Currently < 2 % of the phosphogypsum obtained is utilized. The principal difference in using phosphogypsum compared to FGD gypsum is the need to refine phosphogypsum by recovery operations (washing, flotation, and recrystallization) to remove harmful impurities and to modify its unsuitable particle shape. However, it is simply cheaper to use natural gypsum or FGD gypsum than to purify and process phosphogypsum. The quantity of phosphogypsum obtained annually is nearly equal to world demand for natural gypsum and anhydrite of ca. 100×10^6 t/a [7], [50].

3.4. Fluoroanhydrite

Fluoroanhydrite is a byproduct in the production of hydrofluoric acid from fluorspar and sulfuric acid, to the extent of $(2-3) \times 10^6$ t/a ($n \times M_r$):

$$\underset{(78)}{CaF_2} + \underset{(98)}{H_2SO_4} \longrightarrow \underset{(136)}{CaSO_4} + \underset{(40)}{2\,HF}$$

One tonne of fluorspar produces 1.75 t of anhydrite. Fluoroanhydrite is a product; it is used as a raw material for the gypsum industry only in Germany and some of its neighbors.

3.5. Other Byproduct Gypsums

Calcium sulfate dihydrate is formed in small quantities in the production or treatment of organic acids (e.g., tartaric acid, citric acid, and oxalic acid) or inorganic acids (e.g., boric acid). All these acids are produced by reaction of their calcium salt with sulfuric acid.

The amounts of industrial byproduct gypsums are expected to increase from treating sulfate-containing waste waters and neutralizing dilute sulfuric acids that are produced in the processing of minerals (e.g., zinc ore) and the manufacture of pigments (e.g., titanium dioxide). Especially titanogypsum is obtained in large quantities and can be used in the gypsum industry if it is produced in the titanium dioxide industry with specification and quality standards similar to FGD gypsum. Several 100 000 t are already used in the gypsum industries of Japan, the United States, and Europe [85].

Gypsum scrap from the ceramic industry and metal foundries has likewise not been used so far as a raw material for the gypsum industry, although efforts continue to be made in that direction [53]. The quantities are small and recovery operations are very costly because of the impurities originating from slip casting.

4. Production

Although a dozen industrial processes for the preparation of cementitious calcium sulfates are well known, only a few are used extensively in the industrial countries. The processes characterized by low capital and operating costs, simple design and operation, robust and long-lasting equipment, and uniform high-grade calcined gypsum product subsequently used to manufacture gypsum building components and gypsum plaster are discussed in the following chapter.

Since the two major raw materials – natural gypsum and FGD gypsum – are processed differently, they are discussed separately, as is the refining and processing of phosphogypsum.

4.1. Natural Gypsum to Calcined Products

Natural gypsum is mined by the open-pit method [54] and by underground mining [55]. In open-pit mining the gypsum is recovered by drilling and blasting, mostly on one or more levels. In deep mining, chamber blasting is used [56]. The blasted rock consists of large lumps, containing 0 – 3 % free moisture (quarry water). The amounts of explosives needed are about 250 g/t for open-cast mining and 400 g/t for underground mining.

The coarse rock is conveyed to the crushing plants, normally at the gypsum works, by means of trackless loading and haulage gear. Impact crushers, jaw crushers, and single-roll crushers with screen and oversize return are all suitable for coarse size reduction. Impact pulverizers or

roller mills are used for intermediate size reduction; and hammer mills, ball mills, or ring-roll mills are used for fine grinding. The degree of size reduction is determined by the calcining unit or the intended use of the gypsum:

rotary kiln	0 – 25 mm
kettle	0 – 2 mm
kettle with combined drying and grinding unit	0 – 0.2 mm
conveyor kiln	4 – 60 mm
gypsum and anhydrite for cement	5 – 50 mm

If transport by ship or truck to distant gypsum or cement plants is necessary, the material is reduced to required size for further treatment prior to transport.

Cleaning or beneficiating the blasted rock is no longer common practice, except for gypsum with much Glauber's salt, which is readily removed by leaching with water. This is still done in Britain [54].

Often the mined and crushed rock is homogenized before being calcined. This is done in homogenizing plants with capacities of about one-week's production.

The final stage in gypsum open-pit mining is the restoration of the quarry site and its reinclusion in the environment of the area.

Figure 4. Production of stucco (plaster of Paris, β-hemihydrate plaster) by the rotary kiln process
a) Weigh-belt feeder; b) Rotary kiln with combustion chamber; c) Cyclone (filter); d) Pulverizer

β-Hemihydrate Plasters. Stucco and plaster of Paris are prepared by dry calcination between 120 and 180 °C, either in directly fired rotary kilns or else in indirectly heated kettles, to produce the β-hemihydrate. The kettles may be upright or horizontal.

The *rotary kiln* (capacities up to 600 t/d) is particularly suitable for calcining granular (0 – 25 mm) gypsum rock. This, without predrying, is fed continuously to the kiln in cocurrent flow with the hot gases with a weigh-belt feeder and cellular wheel sluice (Fig. 4). The hot gases are produced in a brick-lined combustion chamber ahead of the gypsum feed. The shell of the rotary kiln is not brick-lined but consists of thick steel plates with steel inserts to ensure an even distribution of gypsum particles across the furnace cross section.

High thermal efficiency is achieved by the direct transfer of heat from the hot gases to the gypsum. The residence time of the gypsum rock in the kiln is self-regulating. It increases with the size of the grains, but complete calcination can be achieved regardless of particle size, to produce β-hemihydrate of uniform quality and invariant properties after fine grinding and air classifying. Any gypsum not dehydrated to hemihydrate at start-up or shut-down is collected in a bin and added in small quantities to the calcined gypsum. Rotary kiln plants are fully automatic and usually can be controlled by one worker.

The externally heated *kettle*, of capacity up to 760 t/d, is the first of a series of similar calcining units heated indirectly. The gypsum is predried and ground to < 2 mm. In modern plants the fine grinding, which used to follow the calcining process, is combined with the predrying and carried out in drying – grinding units to produce particles < 0.2 mm (Raymond mill, Claudius Peters mill, attritor). The properties of the product hemihydrate are shown in Table 8. The phase composition of plaster of Paris is shown in Table 9.

In the 1960s [58], [59] the kettle process was improved and made continuous, especially in England (British Plaster Board Ltd) and North America. Predried and finely ground gypsum is fed continuously from above. As it dehydrates, the gypsum sinks to the bottom, the water vapor set free keeping the gypsum bed fluidized. The calcined gypsum settles at the bottom of the kettle, where it is continuously discharged through a pipe connected to the side of the kettle.

Figure 5 shows a flow diagram for such a plant. The thermal balance is not quite as good

Table 8. Examples of characteristic properties of calcined gypsum [57]

Mode of production	Type of plaster	g plaster per 100 g water	Water to plaster ratio	Setting time, min		Strength of hardened plaster,∗ N/mm^2			Density of hardened specimen, kg/m^3
				initial	final	flexural	compressive	hardness

as for directly fired rotary kilns, but the waste gases are less dust laden. Up to 760 t/d of hemihydrate plaster can be produced in this type of plant.

The *submerged combustion* method – more specifically indirect heat transmission of the externally heated boiler casing combined with direct heat transmission – has been introduced. The advantages are high thermal efficiency and

low energy consumption. Kettles heated only by submerged combustion are being tested at present. Existing kettles can also be fitted with submerged combustion burners, which reduces energy consumption and increases the flow rates. Figure 6 shows a kettle with such a burner that is designed for continuous operation [59].

Figure 7. Production of stucco (plaster of Paris, β-hemihydrate plaster) by the grinding – calcining process
a) Combustion chamber; b) Grinding – calcining unit; c) Separating cyclone; d) Pulverizer

Batch horizontal kettles, with capacities of 5 – 10 t/h, were popular in France (Beau kettles).

Almost the total world production of β-hemihydrate is carried out in plants of the types just described. Today in North america indirectly heated kettles and directly heated rotary kilns are in use in a proportion of about 5 : 1, whereas earlier only kettles were used. In Britain the indirectly heated kettle is widely used; in France, the horizontal kettle; and in Germany, rotary kilns and kettles.

Most of the β-hemihydrate or stucco produced is used in gypsum building components; to a lesser extent β-hemihydrate is used in special building plaster.

Other calcining processes for the manufacture of β-hemihydrate have only occasionally been used industrially. In a grinding – calcining process [60], the raw gypsum is continuously crushed and calcined to β-hemihydrate in a single unit (Claudius Peters; Fig. 7).

A few plants produce β-hemihydrate and to some extent also multiphase plaster in a fluidized bed [61–63] The dried and finely ground gypsum rock is calcined in the stream of hot gases (Thyssen – Rheinstahl). Another development is the indirectly heated, continuously operated horizontal kettle. Externally it resembles a rotary kiln. In this unit the hot gases first pass through a central tube in cocurrent flow and

then through further heating tubes in countercurrent flow. Similar is the continuously operated Holoflite calcining unit, using hot oil or superheated steam as the heat-exchange medium. In this case the gypsum is moved along on a screw conveyor that has hot oil passing through it [64].

Figure 9. Flow diagram for production of projection plaster with a conveyor kiln

Calcined Anhydrous Plasters and Multiphase Plasters. Overburnt plasters are produced in dry calcining processes at temperatures between 300 and 900 °C. For the most part they are calcined anhydrite. There are three reaction stages:

1) AII-s, slowly soluble anhydrite, < 500 °C
2) AII-u, insoluble anhydrite, 500 – 700 °C
3) AII-E, *Estrichgips*, > 700 °C

The properties and final phase compositions of overburnt plaster are shown in Tables 8 and 9.

In overburnt plaster, and also in multiphase plaster, these three stages of reaction have to have a definite ratio, which is determined jointly by the raw material and the calcining process. In some of these processes [1] the gypsum is calcined in such a way that the anhydrite phase is obtained along with the hemihydrate. In other processes the overburnt plaster is produced separately and mixed with β-hemihydrate afterwards. These plasters are designated as multiphase plasters, *Putzgips* in Germany (see Tables 8 and 9).

A modern calcining unit for overburnt plaster and multiphase plaster is the *conveyor kiln* developed by Knauf [65] (Fig. 8). Today, capacities up to 1200 t/d are usual, making it the most efficient kiln used for gypsum. Before being fed to the conveyor kiln, the gypsum rock is crushed to size 4 – 60 mm and split into three or four sieve fractions (e.g., 7 – 25 mm, 25 – 40 mm, and 40 – 60 mm or 4 – 11 mm, 11 – 25 mm, 25 – 40 mm, and 40 – 60 mm). The fractions are piled on the continuous conveyor grate, the smallest on the bottom. The grate, which moves continuously at a speed of 20 – 35 m/h, passes through a calcining hood. There the hot gases are drawn through the gypsum bed by exhaust fans. The top layer can reach a temperature up to 700 °C; the bottom layer, up to 300 °C. The temperature of the heat-resistant plates of the conveyor grate does not exceed 270 °C. The gypsum is not mixed during calcination, and therefore little dust is formed and no dust collection system is needed. About half the hot gases are discharged into the atmosphere as waste gas, issuing from the stack at about 100 °C; the remainder (at ca. 270 °C) is recirculated to the combustion chamber together with air (ca. 230 °C) drawn through the calcined gypsum bed to cool it. The thermal efficiency of such a conveyor kiln is high, greater than 70 %. In Germany and elsewhere conveyor kilns with a total capacity of more than 2×10^6 t/a are currently in operation.

Figure 9 shows a flow diagram of a process producing construction plaster. In addition to a conveyor kiln it also uses a *rotary kiln* in which raw gypsum of small particle size (0 – 4 mm or 0 – 7 mm) is calcined to β-hemihydrate and subsequently mixed with anhydrous plaster that has been ground to the required fineness. In this way, multiphase plasters are produced. They differ from each other in their setting properties and also from β-hemihydrate plaster in that they are coarser (see Table 9 for composition, Table 8 for properties, and Figure 10 for representation as three-component diagram) [1].

Figure 10. Three-phase composition diagram of calcined gypsums [1]
Point P indicates the composition of a multiphase plaster consisting of 27 % β-hemihydrate, 15 % anhydrite III, and 58 % anhydrite II, the composition given in Table 9 for multiphase plaster

Multiphase plasters are used to finish interior walls and ceilings. Since 1965 machine-applied plaster has been produced in large quantities (see Section 5.3) by incorporating chemical additives to one such multiphase plaster. Even pure construction plasters (Saarland construction plaster, southern German *Doppelbrandgips*), which have been used in Germany for years, but which recently have declined in importance, can be prepared in these types of plants. This is also true for the construction plasters used in Latin countries, North Africa, and the Near East [66].

Other calcining plants producing anhydrous plasters operate on the principle of a *countercurrent rotary kiln* (Vernon). For example, in France an overburnt plaster, *surcuit*, is produced and mixed with β-hemihydrate to produce *Paris construction plaster* [67]. In such a countercurrent rotary kiln, the gypsum enters at the end opposite to the combustion chamber and travels into hot gases. The dehydrating gypsum reaches its maximum temperature, (ca. 500 °C), just before exiting the kiln. These kilns, with capacities of 15 – 30 t/h, are sometimes linked together and used to produce anhydrous plaster and β-hemihydrate simultaneously [68]. This improves the efficiency and offers the opportunity of cooling the anhydrous plaster obtained at very high temperatures advantageously. The problem of cooling has also been solved by making use of the planetary cooling system of the cement industry.

α-Hemihydrate. α-Hemihydrate can be produced by wet calcining processes, either under elevated pressure in autoclaves or at atmospheric pressure in acids or aqueous salt solutions between ca. 80 and 150 °C. However, only the autoclave processes have so far achieved industrial importance for the small amounts produced.

α-Hemihydrate from natural gypsum is nearly always batch-processed. For instance, gypsum rock (particle size 150 – 300 mm, >95 % $CaSO_4 \cdot 2\,H_2O$, rocklike) is put in wire baskets, and either stacked in upright autoclaves or wheeled into horizontal autoclaves with capacities of 0.5 – 10 m^3. The autoclaves are heated directly or indirectly with steam at 130 – 135 °C. The heating is carried out so that after about four hours a pressure of 4 – 5 bar has built up. The autoclave is then emptied; the α-hemihydrate formed is immediately transferred in the baskets to a chamber to be dried at 105 °C under atmospheric pressure. It is subsequently ground to the desired particle size and size distribution. Variation in pressure and temperature during dehydration and drying can be used to affect the properties of the products (see Table 8).

α-Hemihydrate is often mixed with β-hemihydrate. For that reason processes have been developed that produce a mixture of α- and β-hemihydrates in a single operation [69]. In one such process the α-hemihydrate is dried in a rotary kiln, which at the same time serves to both calcine the β-hemihydrate and blend the two types of material.

Process Control. Dry gypsum calcining processes are usually equipped with dry *dust collection* systems. The amount of dust formed

depends on the type of calcining unit. For the most part electrostatic filters are used for dust collection, but recently mechanical filters have also been used. Sieves and grinders, as well as conveying equipment, for calcined gypsum are fitted with flat screen-type filters for internal dust collection. The dust collected is added to the calcined gypsum.

The water liberated in the process is discharged as vapor through outlet stacks into the atmosphere. There are no wastes or byproducts. No environmental problems are encountered, provided the processing of the gypsum plaster proceeds normally.

The *energy consumption* of a gypsum plant is the sum of the fuel used in the calcination of the gypsum and the electric power needed to operate the machinery. Table 10 shows the energy consumption of various types of processes based on experience. Mainly oil and gas have been used as the fuel. However, coal is being used increasingly, chiefly in grate firing, pulverized coal firing, and fluidized firing systems [70]. To improve the energy consumption of these units, the design is optimized and the waste heat is utilized. At the same time large modern gypsum plants are increasingly using automatic process control.

4.2. FGD Gypsum to Calcined Products

FGD gypsum is used directly as a major raw material by the gypsum and the cement industries.

4.2.1. β-Hemihydrate and Multiphase Plasters from FGD Gypsum

FGD gypsum is a finely divided powder with less than 10 % surface moisture. It therefore differs considerably in its state of aggregation from natural gypsum and requires treatment not needed for natural gypsum.

To produce β-hemihydrate for the manufacture of gypsum plasterboards and other gypsum building components, FGD gypsum must be dried before calcination. This can be carried out in cocurrent drying units in which the hot gases come into direct contact with the moist gypsum (e.g., flash dryers), or in tube dryers heated indirectly with steam. After drying, the gypsum is calcined to β-hemihydrate in kettels [71], [72].

FGD gypsum used for the production of multiphase plaster and gypsum building plaster must be treated further. Its particle structure, which ranges from cubic (bulk density 1200 kg/m^3) to lath or rod shaped (bulk density 500 kg/m^3), and its narrow particle size distribution (40 – 60 µm) are unsuitable for the production of multiphase plaster [73]. It is this particle structure that is the cause of its thixotropy if it is used as multiphase plaster. As plaster it also lacks smoothness, and its volume yield is too variable.

Agglomeration processes have been developed to modify the particle structure of FGD gypsum and convert it into a lump product. Of all the agglomeration processes – briquetting with a compacting press, granulating with extrusion presses, pelletizing – *briquetting* has proved the most effective and is the most widely accepted. In this process the flue-gas gypsum is compacted in the dry state without addition of bonding agents or additives to produce briquettes 2 cm thick and 6 cm long, comparable to natural gypsum in their mechanical properties [74].

Their point strength exceeds 500 N, and their apparent density is ca. 2.15 g/cm^3. These briquettes are exceptionally abrasion resistant. They can be stored in the open and are unaffected even by frost or rain. In this form all types of FGD gypsum have a bulk density of ca. 1.1 t/m^3 and can be used alone or mixed with natural gypsum.

Figure 11 shows a flow diagram for a plant processing flue-gas gypsum by drying and briquetting. Several of these plants operate in Germany.

The FGD gypsum briquettes can be processed to multiphase gypsum plaster in the calcining units used for natural gypsum.

The extra energy input per tonne of dry $CaSO_4 \cdot 2\,H_2O$ consists of 550 000 kJ of thermal energy and 12 kWh of electrical energy for drying and 10 kWh of electrical energy for agglomeration into briquettes.

Another method for modifying the unsuitable particle structure of calcined FGD gypsum is fine grinding, which also gives a product suitable for production of multiphase plaster and gypsum building plaster [75].

The value of FGD gypsum can be established from a cost comparison between processing FGD gypsum and natural gypsum. A second

Table 10. Examples of characteristic energy data in manufacturing calcined gypsum

major factor is the transport of the FGD gypsum from power station to gypsum plant. In comparison with the transport of natural gypsum from the quarry to the gypsum plant, the transport of FGD gypsum is associated with additional costs, e.g., for intermediate storage due to seasonal differences in production of the power station and consumption of the gypsum plant.

For a gypsum plant the long-term security of supply of FGD gypsum is vital. In times of FGD gypsum shortages it must therefore be possible to fall back on natural gypsum. The surplus quantities of FGD gypsum that will be available in the future in parts of Europe should be placed in intermediate storage locally in artificial deposits as a future raw material reserve. An environmental compatibility study is at present being prepared. With such a gypsum reserve it would be possible to fulfill the requirement of the gypsum industry for an assured long-term supply of raw material over the life-time of the power station [47], [76].

4.2.2. α-Hemihydrate Plaster from FGD Gypsum

FGD gypsum is an ideal raw material for manufacturing α-hemihydrate plaster by the continuous autoclave process (Nitto Gypsum – Knauf). The gypsum is used in its original moist, finely divided state without predrying. In the continuous autoclave process, shown schematically in Figure 12, FGD gypsum having a free water content of 10 % is slurried with water (one part gypsum, two parts water) and pumped continuously into the autoclave where it is dehydrated to α-hemihydrate under controlled conditions (135 °C, 2 h). Additives in the suspen-

sion change the crystal habit of the α-plaster and yield a product of defined, consistent properties. The α-hemihydrate produced is withdrawn as an aqueous suspension and dewatered in a vacuum filter. The product, which has a free water content of ca. 10 – 15 % is immediately dried at ca. 150 °C in an indirectly heated dryer and ground. This dry α-hemihydrate can then be used for all types of α-hemihydrate plasters and products.

Figure 12. Production of α-hemihydrate from FGD gypsum by the continuous autoclave process (Nitto Gypsum – Knauf)
a) Autoclave; b) Expander; c) Vacuum filter; d) Dryer; e) Pulverizer

Today the continuous autoclave process is also used industrially for the processing of finely divided natural gypsum and synthetic gypsum.

Another α-hemihydrate plaster process has recently been developed especially for utilizing lignite FGD gypsum (ProMineral – SICOWA). The moist, finely divided FGD gypsum is mixed with auxiliaries, pressed into stable stackable blocks and converted into α-hemihydrate plaster in large hot pressure autoclaves. The resulting blocks of α-gypsum are dried and ground. Important applications for this type of α-gypsum are the manufacture of self-levelling floor plaster, floor slabs, and mining mortar. Other continuous autoclave processes have ceased operations within a few years (Giulini), never got beyond the pilot stage (ICI), or remained dormant in patents. Processes in which α-hemihydrate is produced without pressure in sulfuric acid, nitric acid, or salt solutions are found in the literature, but they never came into operation. A patent describes a method for producing α-hemihydrate directly from the calcium sulfite of a scrubbing liquor [77]. All efforts to produce an α-hemihydrate plaster similar in its properties to β-hemihydrate plaster have so far been unsuccessful.

4.3. Phosphogypsum to Calcined Products

Moist, finely divided phosphogypsum is a waste from the production of wet phosphoric acid [13]. It is available as filter cake with a free water content of 20 – 30 wt %. The content of impurities is high and the impurities must be removed or rendered harmless by recovery operations such as washing, flotation, and recrystallization before phosphogypsum can be used by the gypsum industry. All phosphogypsums contain inorganic impurities such as phosphates, silicofluorides, and sodium salts. They affect the properties of the gypsum. Organic impurities and small amounts of radiation (^{226}Ra) are present in sedimentary phosphate rocks (Morocco), part of which appears in the gypsum. Magmatic phosphate rocks (Kola) contain no organic impurities and no radioactive matter. The unsuitable crystal shape of all phosphogypsums must be modified by fine grinding or by recrystallization.

The one- and two-stage processes that have been developed for the manufacture of wet phosphoric acid produce different qualities of phosphogypsum. In the *one-stage* processes, phosphogypsum is obtained as dihydrate (dihydrate process, e.g., that of Prayon, altogether representing 84 % of all phosphogypsum produced) or hemihydrate (hemihydrate process, e.g., that of VEBA [78] or Fisons [79], but representing less than 1 %).

In the *two-stage* phosphoric acid processes, either gypsum or hemihydrate is produced in the first stage. In the second stage it is converted to another state of hydration before being removed by filtration. These processes include the hemihydrate – dihydrate process (e.g., Nissan [80]; 15 % of all phosphogypsum produced) and the dihydrate – hemihydrate process (e.g., Central Prayon [81], less than 1 %). Generally, gypsum obtained from the two-stage processes is of better quality in regard to inorganic impurities such as phosphate, fluorine, and sodium.

The gypsum industry is faced with the need for recovery operations if it attempts to use phosphogypsum [82], [83]. Removal of organic impurities, which discolor the gypsum, and of water-soluble inorganic contaminants, which cause efflorescence, involves first remashing the phosphogypsum with water, then sub-

jecting it to flotation, classification (hydrocyclone), thorough washing, and filtering. The radioactivity must be decreased to < 370 bq/kg ($< 10 \times 10^{-9}$ Ci/kg). Up to 5 t of water per tonne of phosphogypsum is consumed. Gypsum purified in this way is obtained as filter cake with a free water content of 20 – 30 %.

For production of β-hemihydrate intended for gypsum building components the filter cake is dried (e.g., rapid dryer from Hazemag, or the contact dryer from Serapic) and then calcined to β-hemihydrate in the same way as finely ground natural gypsum. Today this method is still the principal one used by the gypsum industry in Japan, where this method was developed in 1940 by Yoshino.

For use in gypsum building plaster and multiphase plaster, phosphogypsum is made unsuitable by its particle shape, fineness, and isomorphous acid phosphate impurities. Its particle shape and fineness seriously impair the workability of the multiphase plaster, i.e., the plaster is thixotropic. The cocrystallized acid phosphates cause calcined products to develop *lime sensitivity*, which interferes with setting and development of the strength [84].

In order to overcome these deficiencies the phosphogypsum is dried, calcined, and after addition of aqueous calcium hydroxide suspension simultaneously agglomerated and recrystallized in a pelletizer. Such alkaline-recrystallized pellets are used as starting material for gypsum building plaster and multiphase plaster.

In one process *phosphohemihydrate gypsum* is the starting material. If the process is carried out with adequate care, the phosphohemihydrate is sufficiently pure that the gypsum recovery can be dispensed with. The fine phosphohemihydrate, having a residual water content of ca. 20 – 25 %, is mixed immediately with a calcium hydroxide suspension or calcium hydroxide powder so that the calcium sulfate crystallizes into coarse-grained dihydrate. Part of the moisture and all of the acid phosphate are bound chemically, and the particle size and structure are satisfactory.

The phosphogypsum pellets or lumps thus produced can then be calcined and further processed in rotary kilns or, after grinding, in kettles to produce a β-hemihydrate plaster similar in composition to plaster of Paris. They can be converted on a conveyor grate into overburnt plaster, which consists of coarse particles and is comparable to multiphase plaster. These plasters can be processed into all kinds of machine-applied and premixed plasters.

Such processing methods were developed and put into operation by Knauf in 1962 and 1970. Most other processes designed to use phosphogypsum (e.g., those of Rhône-Progil, Charbonnages de France, Chimie-Air Industrie, Imperial Chemical Industry, Buell) have not resulted in viable commercial operations.

The recovery operations required by phosphogypsum involve additional capital expenditure and operating costs, jeopardizing its competitiveness with natural gypsum and generally rendering phosphogypsum uneconomical for commercial use. The repercussions felt after the first energy crisis, in 1973, because the extra treatment is energy intensive, were an additional set-back.

Unlike flue gas gypsum producers, phosphoric acid producers do not pay for the extra treatment required by the gypsum manufacturer. In summary, the conclusion must be drawn that the chance of phosphogypsum ever being utilized on a large scale worldwide is extremely remote, even though disposal of phosphogypsum is becoming more of a problem [50].

Only Japan has so far managed to continuously use phosphogypsum, an accomplishment favored by its total lack of natural gypsum resources [85]. South Korea also uses phosphogypsum as a source of gypsum.

4.4. Anhydrite Plaster

Anhydrite plaster is produced by grinding anhydrite rock in tube mills or impact pulverizers to a particle size below 0.2 mm. Activators to promote setting are added together with the gauging water. However, the very fine grinding is expensive.

The activators are mixtures of alkali-metal or heavy-metal salts and calcium hydroxide, up to ca. 2 wt % of the anhydrite. Acid activators, e.g., potassium hydrogensulfate or iron(II) sulfate, can also be used [86].

Fluoroanhydrite, a dry fine powder, is neutralized with calcium hydroxide and ground very finely for use as an anhydrite plaster. Sulfates, e.g., potassium sulfate and zinc sulfate, and cal-

cium hydroxide or Portland cement are activators [87], which are usually added and mixed with the anhydrite powder in the factory.

Natural anhydrite and fluoroanhydrite differ from each other in crystal structures. Fluoroanhydrite consists of very small primary crystals that have been agglomerated to secondary particles with a high specific surface area and high reactivity, whereas natural anhydrite consists of large primary particles, which are rendered reactive by fine grinding.

A recently devoloped process for the manufacture of thermal anhydrite from FGD gypsum is the suspension gas calcining process (POLCAL process). The plant consists of one or more preheating cyclones, a reactor with integrated separating cyclone, and a cooler. The conversion temperature is $> 700\,^{\circ}C$, and the residence time of the small gypsum particles in the reactor is a few seconds. Thermal anhydrite from FGD gypsum is used as a binder component in self-levelling floor plasters [47].

5. Use and Properties of Gypsum Plasters and Products and Anhydrite Plasters

5.1. Hydration, Setting, Hardening

Calcium sulfate hemihydrate, anhydrite III, and anhydrite II undergo hydration under ambient conditions, converting into calcium sulfate dihydrate. If hydration is carried out with just enough water to produce a homogeneous, fluid, stable, nonsedimenting slurry, then this mixture sets and hardens because the calcium sulfate dihydrate forms needles that intergrow and interlock.

Much research has gone into the mechanism of hydration. Around 1900, Le Chatelier [88], [89] established the theory of crystallization, which gained universal acceptance [90], [91]. According to this theory the calcium sulfate hemihydrate in water first forms a saturated solution, about 8 g/L at 20 °C. However, this solution is actually supersaturated, because at 20 °C calcium sulfate dihydrate has a solubility of only 2 g/L, and $CaSO_4 \cdot 2\,H_2O$ precipitates.

Cavazzi [93], and later Baykoff [94], put forward a colloid theory, which states that the hydration proceeds via a colloidal intermediate involving formation of a type of gel or an adsorption complex between the calcium sulfate hemihydrate and water. However, this gel has not yet been demonstrated experimentally. The Le Chatelier theory of crystallization has been supplemented by the detection of topochemical reactions taking place during hydration [95]. The two mechanisms are not mutually exclusive, because transformation into dihydrate in both cases takes place via the solution phase. The topochemical hydration is an internal hydration of the hemihydrate particles taking place over very short distances.

Figure 13. Stages of hydration, setting, and hardening of calcium sulfates

Formation of dihydrate crystals conforms to the laws of nuclei formation and crystal growth (Fig. 13). Mixing and wetting of the hemihydrate powder, which causes disintegration of the hemihydrate particles, is followed by a short induction period, after which nuclei begin to form from the supersaturated solution. The accumulation of very small dihydrate crystals with much excess water has been described by Krönert et al. as clustering [96]. Subsequently, after this nucleation, crystal growth begins, which at least initially is accompanied by continuous recrys-

tallization [92]. The rate of nuclei formation is proportional to the relative supersaturation (von Weimarn's theory), and the rate of crystal growth is proportional to the absolute supersaturation (Nernst – Noyes equation). Hemihydrate is converted directly into dihydrate; there are no intermediate stages. Anhydrite III is converted via the hemihydrate, and anhydrite II is converted directly into dihydrate, without anhydrite III or hemihydrate intermediates. If the proportion of water is correct for setting and hardening, the slurry hardens by forming a dihydrate structure, a final crystallization, which according to LUDWIG et al. [97] consists of intergrown, overgrown, and interlocking dihydrate crystals and inclusions of unhydrated components. Excess water can be removed by drying.

The rate of hydration of β-hemihydrate as shown in Figure 14 is indicated by combined water content, intensity of the X-ray diffraction, and rise in temperature due to the heat of hydration [96].

Figure 14. Rate of hydration of β-hemihydrate as indicated by combined water content (—-), intensity of X-ray diffraction (– – –), and temperature increase from heat of hydration (. . .) [98]

There are many ways in which these processes of hydration, setting, and hardening can be applied in practice. Parameters for characterizing these processes are the water-to-plaster ratio on mixing, the consistency of the mixture, the initial and final set, the rate of strength development, and the strength and density of the final dry gypsum product.

The method of manufacture of the plaster influences the gypsum technology to a very large extent. For instance, β-hemihydrate from a rotary kiln requires more water to produce a fluid slurry of uniform consistency than does plaster from a kettle. The latter, in turn, requires more water than multiphase plaster, which, in turn, requires more than autoclave plaster. This water-to-plaster ratio (water capacity of the gypsum plaster), an inverse of the quantity of gypsum plaster in grams per 100 g of water, is related to the strength and density of the set and hardened gypsum product.

α-Plasters, which are workable with little water, can be simply turned into gypsum products of high strength and high density. However, these products are avoided in the building industry on account of their brittleness.

β-Plaster and multiphase plaster require more water than α-plaster to obtain a fluid consistency. They produce products of average strength, higher elasticity, and lower densities, and are used universally in the construction industry.

The particle shape, particle-size distribution, and specific surface area also determine the quantity of water required to give a specific consistency. Generally, very fine plaster requires more water than coarse-grained plaster. Rod-shaped particles also increase the amount of water needed. β-Hemihydrate particles may disintegrate on first contact with water, breaking up into a multitude of very fine loose particles, thus changing their particle size distribution [99]. The particle size distribution of multiphase plasters determines their workability to a great extent.

When stored, calcined gypsums are subject to changes in their properties, called *aging.* This aging is caused to some extent by the uptake of water vapor from the air. The degree of aging affects the water needed for given consistency; more water is needed for fresh calcined gypsum than for aged. If a considerable amount of water vapor is adsorbed, dihydrate nuclei may form, accelerating the hydration process. However, the reactions taking place on aging have not yet been entirely elucidated [98], [100]. Natural aging of calcined gypsum produces gradual changes in the properties of the plaster over a period of months. To avoid this, methods have been developed to bring about aging artificially, so that the plaster undergoes no significant changes during storage. One process is called aridization: calcium chloride or similar salts are added in quantities up to about 0.2 wt % to the raw gypsum before calcination [101]. Aging of calcined gypsum is also achieved by injecting small quantities of water containing a wetting agent to prevent the formation of a dihydrate [102], [103].

The mixing and gauging of calcined gypsum with water to form a slurry of specific consistency can be affected by various wetting agents. Most of these, called *plasticizers* or water-reducing agents, lower the water demand. They include alkylarylsulfonates, lignosulfonates, or melamine resins [104]. It is also possible to increase the water requirement by adding flocculating agents, e.g., polyethylene oxide [105]. Chemicals that thicken, e.g., cellulose and starch ethers, can be added to stabilize the water – plaster slurry or prevent sedimentation and segregation; however, these have little effect on water demand [106].

Setting and hardening can be accelerated or retarded by numerous additives [107], [108]. Many inorganic acids and their salts are useful as *accelerators*, especially sulfuric acid and its salts. Calcium sulfate dihydrate is regarded as a special additive in this respect. Finely divided, it acts as a strong accelerator and therefore must be completely removed when raw gypsum is calcined. The accelerating effect of these substances is due to an increase in solubility and the rate of dissolution of the calcined gypsum and to an increase in the rate of nuclei formation.

Retarders are usually organic acids [109] and their salts and organic colloids that are the decomposition and hydrolysis product of biopolymers such as proteins as well as salts of phosphoric acid or boric acid. The mechanism of retardation varies: high molecular mass colloids prolong the induction period because they are nuclei poisons. Other retarders slow down the rate of dissolution of the hemihydrate or the growth of the dihydrate crystals. The hydration of anhydrite II usually does not have to be retarded since it is slow enough and almost always requires acceleration.

In every case, temperature affects the rate of hydration of plaster, the rate increasing up to ca. 30 °C, after which it decreases [110].

The *strength* of set dried gypsum is directly proportional to its density, and therefore depends only on its porosity or, less directly, on the water-to-plaster ratio and the size and structure of the pores [111], [112]. The strength is affected by moisture or additives without a change in density. The strength of gypsum products with a moisture content exceeding 5 % is only about one half that of air-dried gypsum products. When a gypsum product dries, the strength begins to increase below 5 % moisture content, becomes evident around 1 % moisture content, and reaches its final value in the region of its equilibrium moisture content [11].

Persistently moist conditions reduce strength, because crystalline and textural changes, especially recrystallization, take place as a result of the solubility of gypsum in water [113]. The deformation or creep of moist gypsum products under mechanical stress is likewise the result of structural change. Additives induce a change in structure by changing the crystal habit of the dihydrate so that without a change in density strength is changed even in the dry state.

An extreme example of reducing strength is the effect of citric acid, commonly used as a retarder. Used sparingly, less than 0.1 %, it does have a retarding effect and lessens the strength only slightly. More, say, above 0.2 %, changes the crystal habit of the dihydrate to such an extent that hardening of the gypsum is no longer possible because the crystals no longer interlock and intergrow [114].

Murat [115] has studied the morphology of natural and synthetic calcium sulfate dihydrates with up-to-date techniques and the effects of additives upon the crystal habit of the dihydrate.

5.2. Prefabricated Gypsum Building Components

Prefabricated gypsum building components are manufactured in large quantities: plasterboards, partition panels, ceiling tiles, and fiber-reinforced boards. These are light, porous, dry, and nonbrittle products possessing excellent workability. β-Hemihydrate is the starting material for all these because it sets quickly and easily meets the building industry's demand for certain properties for the finished product.

The plants for the manufacture of gypsum building components are usually built adjacent to gypsum works.

Gypsum *plasterboards* are large thin gypsum panels covered with cardboard; they have a density of 750 – 950 kg/m^3. They are manufactured by feeding β-hemihydrate plaster into a continuous mixer from controlled feeding devices, mixing it continuously with water and additives, e.g., adhesives, to form a homogeneous and rapidly setting slurry. This slurry is spread on a con-

tinuous sheet of cardboard about 0.5 mm thick (200 – 300 g/m^2). The slurry is then covered with a second sheet of cardboard and passed over a molding platform to be shaped into a completely encased strip, 1.20 – 1.25 m wide and 9.25, 12.5, 15.0, 18.0, or 25.0 mm thick. This strip of gypsum plasterboard, initially soft, hardens within minutes and is cut into separate panels. These panels, approximately one-third of whose weight is free water, are dried immediately in a continuous tunnel dryer heated indirectly with steam or directly with gas or oil. The finished gypsum plasterboard, consisting of a gypsum core tightly encased and bonded to cardboard, is considered to be a laminated building material.

Many different types of gypsum plasterboard are manufactured, depending on their intended use. Distinctive features are size, edge configuration, weight, water resistance, structural behavior, and strength. Gypsum plasterboards with specific fire-resistant properties incorporate fiberglass. The noncombustible gypsum lightweight board makes use of a laminate of glass fiber mat with a lined-on glass silk scrim to replace the cardboard [116]. Modern plants for the manufacture of plasterboards have a capacity of about (20 – 40) $\times$ 10^6 m^2/a and an annual consumption of 150 000 – 300 000 t of hemihydrate plaster.

Plasterboard is used in interior finishing, e.g., for wall and ceiling paneling. It is screwed to wooden or metal frames or pasted on masonry or concrete with special building plaster (adhesive plaster, the German *Ansetzgips*). The joints are covered and finished paperless or with special paper and joint filler to form a smooth surface. Plasterboard can also be used for the construction of dismountable partitions and lightweight dividing walls having various characteristics (weight, sound proofing, fire resistance) in concrete or steel-framed buildings as well as in prefabricated dwellings. Plasterboard is factory processed into special-sized panels, coffers, or lightweight laminated panels with intermediate layers of polystyrene or polyurethane (insulating board). Multilayered plasterboards are used for dry floorings and for the construction of lift shafts. Factory-made tiles with decorative surface finishes such as plastic sheet, special coats of paint, or aluminum foil to prevent water vapor transmission are available.

Gypsum *partition panels* consist of set gypsum plaster. To produce them β-hemihydrate plaster is mixed with water (water-to-plaster ratio 0.9 – 1.0) and the slurry, which sets quickly, is poured into molds. After 5 – 8 min the panels are removed from the molds and dried [117].

The standard size of gypsum partition panels is 500$\times$666 mm, with a thickness of 60, 70, 80, or 100 mm and a density of 700 – 900 kg/m^3. They are used in interiors as lightweight dividing walls, the tongue and groove joints being bonded with joint plaster. The partition walls can be single or multilayered. Characteristic features are low weight, average to good sound insulation, and excellent fire resistance.

Gypsum *ceiling tiles* are produced by mixing β-hemihydrate, water, and small amounts of glass fiber and pouring the slurry into rubber molds. The molds allow for individual designs.

Ceiling tiles are used as decorative tiles, ventilation tiles, heating tiles, or sound-proofing tiles with mineral wool bonded on the back. They are screwed to a base frame and fitted into the framework. They are normally 625 $\times$ 625 mm in size and weigh between 10 and 20 kg/m^2.

Gypsum *fiber board* and fiber-reinforced gypsum elements are another group of gypsum building components manufactured from hemihydrate plaster and paper, glass, or other fibers [118–122]. Glass fiber can be incorporated as mat or web [123]. These components contain up to 15 wt % fiber, evenly distributed in the plaster. They have an apparent density between 800 and 1200 kg/m^3.

Factories for the manufacture of gypsum partition panels and ceiling tiles have capacities up to 10^6 m^2/a, consuming about 50 000 t/a of hemihydrate plaster, and those for gypsum fiberboard up to 10 $\times$ 10^6 m^2/a, consuming the same amount of hemihydrate. The most widely used gypsum fiberboard is Fermacell, which is produced in central Europe in quantities of 20 $\times$ 10^6 m^2/a.

5.3. Gypsum Plaster

Calcined gypsum is used for plastering. Multiphase plaster (see Table 9) is most suitable because its phase composition results in quick initial setting and gradual final setting; smoothness, plasticity, and high coverage; single-coat appli-

cation; rapid drying of the finished plasterwork; and suitable density and high strength.

β-Hemihydrate plaster without additives is not suitable for plastering because the initial setting occurs too late and the final setting too early. Also its particle size distribution is not suitable for plaster. However, additives permit β-hemihydrate to be made into certain types of plastering material, known as retarded hemihydrate gypsum plaster and premixed lightweight gypsum plaster. Because of inadequate setting properties, lack of smoothness, and insufficient coverage, α-plasters are not used in construction [11], [124].

Over the past twenty years considerable progress has been made in Germany towards development of a factory-made machine-applied gypsum plaster. Ordinary multiphase plaster is used as the starting material. Mixed with additives and aggregates it is processed into a material that can be used for continuous machine application in single coats. The rate of setting and the hardening process have been adjusted to suit the longer working cycle for material applied over a large surface area. Too rapid water uptake is controlled by adding water-retaining hydrophilic colloids such as methyl cellulose. In this way the soft plaster slurry remains plastic until the work has been completed, resulting in better bonding to the base. The uniformity of the properties and the homogeneity of these plasters are particularly good when they are manufactured in large plants.

Such plants are equipped with high-capacity mixing and handling devices (see Fig. 9) and can produce up to 400 000 t/a. At the construction site the dry plaster is fed continuously into the plastering machine where it is mixed with water at a metered rate to form a slurry applied in a single coat to the base by means of a screw pump and hose. A smooth and even surface is obtained with an electrically powered felting tool (e.g., Power Float, Gipsoglätt).

Plastering machines operated inside buildings are supplied with plaster directly from outdoor bins or containers by pneumatic conveyor pumps through flexible hoses.

Premixed gypsum plasters (bonding plaster, lightweight plaster), factory-processed from β-hemihydrate plaster (or multiphase plaster) containing additives and aggregates, e.g., expanded perlite or vermiculite, are worked batchwise on site. The plasters are mixed with water and applied in one coat on all types of concrete and masonry. Premixed plasters already contain the necessary additives to ensure good workability. Only water need be added by the plasterer. The application properties of these plasters are listed in Table 11.

In some countries, especially in Great Britain, the two- or three-coat method of plastering is still employed. The undercoat is browning plaster, a factory-processed hemihydrate plaster containing a retarder, which is mixed with sand or expanded perlite either in the factory or on the building site. It takes several hours to set, i.e., far longer than premixed plaster. The next day a smooth finishing coat of plaster of Paris and hydrated white lime is applied.

In France, Spain, some countries in North Africa and the Near East, and to some extent in southwest Germany, especially in the Saarland, pure multiphase plaster containing no additives (Paris construction plaster, southern German *Doppelbrandgips*, Saarland multiphase plaster) is used for single-coat and multicoat plasterwork. In countries with a dry climate, e.g., Iran, multiphase plaster is also used as mortar for brickwork and for external claddings.

5.4. Other Uses

Anhydrite capable of setting and α-hemihydrate plaster are extensively used as binders for mining mortar and as flooring plaster, uses where their brittleness is not a handicap [125].

Substantial amounts of natural anhydrite are consumed by the mining industry for the construction of roof supports for galleries and ventilating air structures in coal mines. Dry *mining anhydrite* having a specified particle size distribution, e.g., 0 – 6 mm, and containing an accelerator is used in underground coal mines worked by the long-wall method. With the aid of large blowers the anhydrite is conveyed pneumatically through hoses and wetted at the site of use before being sprayed in layers to form a barrier. The anhydrite barriers rapidly develop a high initial compressive strength of about 15 N/mm^2, their strength exceeding 40 N/mm^2 after 28 d. They serve to support the gallery and roofs in the roadways [126]. α-Hemihydrate plaster is also used as a binder for mining mortars [127].

Table 11. Application properties of projection plaster, bonding plaster, and premixed plaster∗ [10]

Property	Projection plaster	Bonding plaster	Lightweight plaster
Water : plaster ratio	0.45 – 0.65	0.60 – 0.80	0.55 – 0.75
Initial setting, min	60 – 120	40 – 90	40 – 90
Final setting, min	120 – 240	60 – 120	60 – 120
Strength of set and hardened gypsum, N/mm^2			
Flexural strength	1 – 2	1 – 2	1 – 2
Compressive strength	2.5 – 5	2.5 – 4	2.5 – 4
Apparent density of dry gypsum, kg/m^3	1000 – 1200	850 – 1000	900 – 1100
Coverage, m^2 per 100 kg of plaster	> 60	> 120	> 110

∗ Tests conform to DIN standard 1168 [57].

Finely ground natural anhydrite, processed fluoroanhydrite and α-hemihydrate plaster, all capable of setting, are used as binders for self-levelling floor plasters. When used for laying floor screeds, the cementitious material is first mixed with sand in the proportions of 2 : 5 and then batch-mixed with water in a pan mixer until it attains a stiff consistency. Piston pumps and hoses pump the mix to the different floors and rooms, where it is spread on the floors. More recently α-hemihydrate plaster, with or without additives, mixed with water to form a fluid slurry, has been used as machine-applied floor plaster (self-levelling floor plaster). Since calcium sulfate floor screeds do not shrink, they can be laid free of joints and cracks over a large surface area.

Substantial quantities of natural gypsum, FGD gypsum, and anhydrite rock are used as a retarder for Portland and blast-furnace *cements.* In compliance with German (DIN) standards, the maximum permissible calcium sulfate content of cement is 3 wt % SO_3 for Portland cement and 4 wt % SO_3 for blast-furnace cement [128]. Gypsum rock, FGD gypsum briquettes, or anhydrite rock, or a mixture with a particle size range 5 – 50 mm, is directly added to the cement clinker before grinding. It is then present in the cement in a finely divided reactive form [129]. More than 50 % of the entire gypsum and anhydrite rock production is consumed by the cement industry (see Chap. 7).

In the Russia a *gypsum cement* mortar has been manufactured by calcination of raw gypsum in combination with certain types of cement and active silica. Because of its water-resistant properties, this mortar was used for the production of prefabricated washrooms, occasionally also for exterior wall elements of prefabricated cottages. However, pure gypsum building components have not found widespread use externally because of the solubility of gypsum in water [12], [130], [131].

α-Hemihydrate is used as a high-strength *molding material* for roofing tile, cast metal, and dental materials [15]. Mixed with β-hemihydrate, α-hemihydrate is the favored molding plaster – especially for ceramics – because its expansion on setting and the strength and absorbency of the final mold can be varied by varying the $\alpha : \beta$ hemihydrate ratio [132]. Addition of high molecular mass compounds perhaps improves the stability of gypsum molds without adversely affecting the plaster. Molding plaster is also used to make surgical casts and orthopedic bandages.

Calcium sulfate dihydrate is used as a soil stabilizer and to displace sodium in soils too high in sodium salts, e.g., those soils flooded by seawater. It also serves as a fertilizer in soils deficient in sulfur, especially in North America [133].

The classical Müller-Kühne process (gypsum – sulfuric acid – cement process) has once again become of interest for treating secondary materials such as unrefined calcium sulfite and calcium sulfate from FGD or SAP spray absorption residues (OECD Amber List AB 150) [52], gypsum wallboard or plasterboard from demolished buildings (OECD Green List GG 20) [52], or fly ash. Today in Wolfen, Germany, 100 000 t/a of cement is produced by the Müller – Kühne process [134].

Unrefined calcium sulfite and calcium sulfate from FGD or SAP spray absorption residues, together with fly ash and activating additives, can be converted to a stabilized back-filling material for landfills and mining caverns [135].

The Merseburg process for the manufacture of ammonium sulfate from natural gypsum or phosphogypsum has never been important because the demand for ammonium sulfate has always been met from the large quantities arising as byproduct in the chemical industry [136].

Anhydrite III is an effective drying agent (Drierite) in laboratories and in industry.

Fillers made from FGD gypsum have been investigated thoroughly and their application in adhesives, paints and plastics gave good results. In principle, it is possible to produce calcium sulfate fillers from FGD gypsum, but the economic situation compared to competitive fillers is unsatisfactory [137]. Also coating pigments produced from FGD gypsum for the paper industry have been developed, showing new fields of application of FGD gypsum outside the construction industry [138]. Natural gypsum and anhydrite are insufficiently pure and therefore not suitable for producing fillers and coating pigments. In the beverage industry, especially breweries, pure natural gypsum is used to obtain and standardize the desired water hardness (→ Beer, Chap. 2.5.). Processes developed in the United States and Japan for the manufacture of calcium sulfate whiskers have not yet become established [139].

Pure finely ground anhydrite has found a ready market in the glass industry as a substitute for sodium sulfate because of its low price.

5.5. Properties of Gypsum Building Products Installed in Situ

Gypsum building materials are suitable for the construction of non-load-bearing interior finishes in dry locations. Gypsum building components and prefabricated units are dried at the factory. Gypsum plasters dry after application, with ventilation within a few days. These plasters adhere to the base well [140], [141]. Once gypsum building materials are sufficiently dry, i.e., moisture content < 2 %, they can be decorated immediately with interior coatings, wallpaper, ceramic tiles, and other facings. The surfaces of gypsum building materials are inert [142].

Table 12 summarizes some of the most important properties of gypsum building products installed in situ [10], [143]. Set and hardened gypsum has low density and high pore volume and thus has a low thermal conductivity. The large pore size allows rapid absorption and desorption of water vapor, resulting in high breathing capacity. Gypsum walls and ceilings in living and working rooms feel warm to the touch; they do not sweat. Figure 15 shows a scanning electron micrograph of the structure of set and hardened gypsum.

Table 12. Gypsum building materials and examples of their properties

	Plasterboard, 9.5 mm thick	Finished gypsum projection plaster
Apparent density and porosity		
Density, kg/m^3	900	800 – 1200
Pore volume, %	60∗	50 – 65
Pore radius, µm	ca. 99 % > 0.05	ca. 99 % > 0.05
Climatic properties		
Heat conductivity λ, WK^{-1}m^{-1} (DIN 4108)	0.21	0.35
Heat penetration coefficient b (equivalent)		
1/2-h test, J s$^{-1/2}$ m^{-2} K^{-1}	412	1200
2-h test	489	1400
Resistance to transmission of water vapor μ (DIN 4108)	8	10
Water vapor absorption coefficient a, m/h		
untreated surface	2.29	
rough fiber coated	2.98	2.5
wallpapered	2.66	
Heat expansion and equilibrium moisture content		
Linear coefficient of thermal expansion α_t, K^{-1}	(13 – 20) $\times 10^{-6}$	20 $\times 10^{-6}$
Equilibrium moisture content at 20 °C and 65 % relative humidity, wt %	0.6 – 1.0	0.3
Modulus of elasticity, N/mm^2	2000 – 2800	2800

∗ Core.

Gypsum building materials have volume stability and undergo only slight changes in size with variations in temperature or moisture content. Their equilibrium moisture content is below 1 %; however, permanent wetting and continuous exposure to temperatures above 60 °C change the crystal structure, and should be avoided.

Gypsum building materials promote fire protection because of the combined water of the dihydrate, which, in case of fire, evaporates, not allowing the other surface of the gypsum to reach much above 100 °C. Plasterboard and fiber-reinforced gypsum boards retain their structural

integrity during exposure to fire because of the fibers in the material [9], [144].

Figure 15. Structure of set and hardened gypsum (scanning electron micrograph). The structure shown in the photograph of set hemihydrate plaster is typical of rehydrated gypsum: the characteristic features are determined by needle-like particles that interlock and intergrow and by the high degree of porosity

6. Material Testing and Chemical Analysis

6.1. Standards

Today there are international standards for gypsum products (ISO – International Standards Organisation), European standards (CEN – Comité Européen de Coordination des Normes), and national standards (e.g., DIN, Germany; AFNOR, France; B.S., United Kingdom; ASTM, United States; J.I.S., Japan).

Eurogypsum, the Association of European Gypsum Industries, through its scientific and technical committee, constantly exchanges information with the ISO [145] and RILEM, the International Union of Testing and Research Laboratories for Materials and Structures. The German standards for gypsum comprise material standards [57], [146–149] and application standards [150–163].

EN standards for gypsum building materials are in preparation. In future, quality management and assurance sytems that comply with ISO 9000 – 9004 will be introduced into the gypsum industry.

6.2. Testing

The DIN standard test methods for gypsum building plasters comprise tests on particle size by sieving, initial set with a water : plaster ratio defined by the water capacity of the plaster or the spread in a flow table test, flexural strength, compressive strength, and hardness. A test for bond strength, e.g., for bonding plaster to concrete, is also recommended. Gypsum partition panels and gypsum ceiling tiles are characterized by apparent density, dimensions, weight, and breaking load. Plasterboards are characterized by dimensions, weight, breaking load, and permanent deflection after specified loading and unloading.

A method for determining the Blaine specific surface area is used for comparative testing [164]. A simple and inexpensive device for the determination of impact strength can be used for comparative and routine testing, especially for building components [165], [166].

The ceramic industry determines additional properties, such as setting and final expansion and water absorption coefficient. A standardized vacuum mixer is used to gauge the gypsum slurry and to remove air bubbles from the mixture [167].

Classification of gypsum building materials with regard to their behavior during fires is set out in DIN 4102. Gypsum building materials come within Class A, rated as noncombustible building materials. Materials with no combustible components (such as plaster, partition panels, and ceiling tiles) are classified as Class A 1. Gypsum plasterboard is classed as Class A 2. For materials classified under Class A 2 there are limits for smoke density and toxicity.

Gypsum building materials and components that comply with DIN 4102 are ideal for structures ranging from fire-retardant to highly fire-resistant walls, partitions, ceilings, steel columns, and supporting beams. Test certificates issued for built-in components are based on compliance with Classes F 30, F 60, F 90, F 120, and F 180 – fire retardant to highly fire resistant. The figures 30 – 180 denote the fire resistance rating (period of time in minutes) of the components for a given temperature – time curve.

6.3. Chemical Analysis

Conventional chemical analysis [3] is used in arbitrational analysis. Free water content in raw gypsum, calcined gypsum, and set and hardened gypsum is determined by drying at 45 °C. Combined water content is determined by drying at 360 °C.

Calcium sulfate in solution is qualitatively determined by precipitation of syngenite, $CaSO_4 \cdot K_2SO_4 \cdot H_2O$.

Today the following methods of analysis are used for routine quantitative testing in the laboratories of the gypsum industry: complexometric titration of calcium and magnesium; flame photometry for sodium and potassium; and atomic absorption for sodium, potassium, magnesium, calcium, strontium, iron, aluminum, and sulfate, the last indirectly, via barium [168]. The phosphates contained in phosphogypsums are determined spectrophotometrically or gravimetrically with ammonium molybdate. Water-soluble, citrate-soluble, and total phosphates are distinguished. Fluorine can be determined titrimetrically. Organic substances can be determined by oxidation with potassium permanganate. acidity is determined by titration with alkali using methyl orange or bromophenol blue. Calcium sulfite is determined via SO_2; chlorine, by the Volhard method or with a chloride electrode.

6.4. Phase analysis

Phase analysis differentiates between dihydrate, hemihydrate, anhydrite III, and anhydrite II, including its three reaction stages AII-s, AII-u, and AII-E. This differentiation of calcined gypsum according to phases is not possible by chemical analysis.

Phase analysis can be carried out by X-ray diffraction, infrared spectroscopy, microscopy, and calorimetry. However, it takes considerable experience to reach ± 5 % accuracy [169]. The conventional method in any industrial laboratory is the gravimetric determination utilizing the differing rates of hydration [1], [3], [170], [171].

The determination of dihydrate is not especially accurate, particularly when small quantities (< 5 %) are involved. In such cases, however, an exact determination is possible by differential thermal analysis [172], [173].

The determination of anhydrite II by exposure to moisture is a matter of definition. Thus the anhydrite hydrating within 3 d is designated as AII-s, anhydrite hydrated in 7 d as AII-u, and anhydrite that remains nonhydrated after 7 d is assigned to the nonhydrated constituents and can be determined by an additional measurement. (By the addition of a 1 % aqueous potassium sulfate solution in place of distilled water the seven-day period can be reduced to a few hours [1].) The stages AII-s and AII-E can be distinguished from each other by measurements of the pH value, which for AII-E is > 9, but is otherwise 6.

Distinction between α- and β- hemihydrates is not possible by hydration methods. Today α-hemihydrate and β-hemihydrate are usually determined by microscopy, the quantitative proportions are simply estimated.

7. Economic Aspects

The estimated world consumption of natural gypsum and natural anhydrite in the gypsum and cement industries was ca. 95×10^6 t/a in 1995.

The cement industry, as the largest consumer of raw gypsum and raw anhydrite, used ca. 55×10^6 t/a for a world cement production of 1400×10^6 t in 1995.

The gypsum industry uses ca. 40×10^6 t/a natural gypsum and anhydrite and ca. 5×10^6 t/a FGD gypsum. Less than 2×10^6 t/a of phosphogypsum is used, mainly in Japan, Korea, and Europe. Titanogypsum and fluoroanhydrite consumption is less than 10^6 t/a worldwide.

The most important gypsum building materials are gypsum plasterboards with a per capita consumption of 8 m^2/a in the United States; 6 m^2/a in Japan; and 2 m^2/a in the EU, with the highest consumption in France and Great Britain (ca. 3 m^2/a), and the lowest in Spain and Portugal (0.35 m^2/a). Machine-applied plaster is important in Central Europe, and multiphase plaster in Spain, Italy, North Africa, and the Near East.

Since 1985 the demand for calcium sulfate has increased at an average annual rate of 5 % in Asia, 3 % in Western Europe, and 1 % in North America [174].

The gypsum and cement industries will remain the prime consumers. In only a few countries, perhaps China and the countries in Eastern Europe, the states around the Persian Gulf, and some rapidly developing areas in the Far East, is gypsum consumption expected to rise in response to increased building activities.

8. Recycling and Disposal

As with other materials, the life cycle of the products of the gypsum building materials industry consists of winning of raw materials and their treatment, production, use, and recycling or disposal:

- Gypsum-containing *production residues* are recycled in the production plant by returning them to the production stream.
- Building site *residues from construction plasters* that are free of foreign components and sorted according to type can be returned to the producer or sent to regional collection facilities.
- Regional collection facilities are planned for building site *residues from gypsum building components* that are free of foreign components. These residues will be treated and then returned to the production process.
- *Residues from demolition and renovation* are to be collected at treatment plants and so processed that they become suitable for recycling. Plants of this type are already in operation in Germany.
- Used *gypsum molds and models* from the ceramics industry, provided they are free of foreign components, can be taken back by agreement with the gypsum supplier and used as secondary raw materials.
- Used *models from dental laboratories* and from modelling can be treated in the same way
- Non-recyclable gypsum-containing residues can be disposed of in landfills for building wastes. In Germany this is governed by the TA-Siedlungsabfall and the Kreislaufwirtschafts- und Abfallgesetz [10], [175], [176].

In general, for the disposal of gypsum-containing wastes in landfills, the influence of the gypsum residues on ground water and surface water is comparable to the influence of natural gypsum in deposits.

1. Introduction

Malignant tumors represent one of the most common human diseases worldwide. Based on an estimation made in the United States, cancer will become the leading cause of death in the year 2000 [1].

Unfortunately, the subset of human cancer types that are amenable to curative treatment still is rather small. Although there is a tremendous progress in understanding the molecular events that lead to malignancy and many agents are known that effectively kill cancer cells, progress in development of clinically innovative drugs that can cure humans is slow [2], [3].

The heterogeneity of malignant tumors with respect to their genetics, biology, and biochemistry as well as primary or treatment-induced resistance to therapy hamper curative treatment [4], [5].

Searching for antineoplastic agents with improved selectivity to malignant cells remains the central task for drug discovery and development [5], [6].

According to a survey published in 1997 more then 315 drugs are under development in the United States for the treatment of cancer. This figure includes 42 drugs for treatment of lung cancer, 58 for breast cancer [8], [9], 60 for treatment of skin tumors (60), 36 for prostate cancer, and 35 for colon cancer.

In 1997 more than 1500 Americans are expected to die of cancer each day and more than a million new cases will be diagnosed with overall medical costs of $\$35 \times 10^9$. The total disease costs are estimated to sum up to more than $\$100 \times 10^9$ per year in treatment expenses and lost wages.

Increase in the incidence of cancer, mostly as a result of an aging population, is the driving growth in the marketplace. However, new medicines like hormone-analogs have lead to decrease in severity of the side effects of cancer therapy and have spurred wider use. According to a review [11] of ca. 90 approved anticancer drugs, more than 60 % are of natural origin or modeled on natural products parents. Cancer chemotherapeutics can be grouped according to their pharmacological and mechanistic profiles into

Antimetabolites
Alkylating agents
DNA-intercalating (agents) antibiotics
Mitose inhibitors
Signaltransduction-inhibitors

Two primary events in cell proliferation are DNA replication and cell division [12], [13]. The cell cycle has been divided into four sequential phases (G_0, G_1, S, M) and the cytostatics vary in the way they interfere with the cell cycle. Phasespecific agents/drugs, e.g., those interacting in G_1, S- or M-phase, are the mitose-inhibitors vincristine or vinblastine or the antimetabolites methotrexate or cytarabine, attacking in the S-phase. Alkylating drugs such as cyclophosphamide, cisplatin, or carboplatin inhibit and damage the cell in all phases and are thus phase unspecific. In general cells in the resting phase (G_0) are insensitive.

Approximately 70 % of patients diagnosed as having cancer have metastatic disease, i.e., dis-

ease that has spread beyond the primary site at the time of diagnosis [15]. However, the steady progress made in the treatment of cancer with drugs has contributed to the curing of an increasing proportion of patients with metastatic disease. The greatest change and improvements in cancer treatment have occurred because of the discovery and clinical development of drugs and the demonstration that metastatic cancer can be cured by these agents. Drugs, such as cytoxan, adriamycin, vincristine, *cis*-platinum, and bleomycin, all developed since 1960, are now regularly used by physicians to treat patients who would have been considered incurable a short time ago.

This article details the pharmacology and clinical use of the major classes of anticancer agents, including (1) antimetabolites, (2) alkylating agents, (3) anthracyclines and analogs, (4) other antitumor antibiotics, (5) antitubulin agents, (6) platinum complexes, (7) antihormones, and (8) signaltransduction-inhibitors. In each case, special emphasis is given to the progress made in developing clinically useful drugs and analogs that retain antitumor activity while decreasing host toxicity.

2. Antimetabolites

2.1. Methotrexate

Folic acid analogs comprise a class of antineoplastic agents of which methotrexate has gained the most widespread clinical use. These agents were the first to produce impressive remissions in acute leukemia [16] and cures in choriocarcinoma in women [17].

Reduced folates (tetrahydrofolates) are the biologically active form of folates required as cosubstrates in one-carbon transfer reactions. Included in these reactions are several important enzymatic steps in the de novo synthesis of purines and pyrimidines.

Methotrexate (NSC-740) [*59-05-2*], *N*-(4-{(2,4-diamino-6-pteridinyl)methyl]methylamino}benzoyl)-L-glutamic acid, $C_{20}H_{22}N_8O_5$, M_r 454.46, is a 2,4-diamino, N^{10}-methyl analog of folic acid that is capable of inhibiting certain folate-requiring reactions.

Methotrexate

Most importantly, methotrexate can inhibit dihydrofolate reductase (DHFR, $K_i = 10^{-11}$ M), a key enzyme for the maintenance of biologically active intracellular reduced folate pools. The folate-requiring reactions utilize reduced folates, and all reactions except that catalyzed by thymidylate synthase maintain folates in a reduced state during carbon transfer. Thymidylate synthase, which catalyzes the methylation of deoxyuridylate to thymidylate (required for DNA synthesis), requires the transfer of a carbon group from the folate cofactor N^{5-10}-methylene tetrahydrofolate with resultant oxidation of the folate to dihydrofolic acid. Oxidized folates must be reduced to the tetrahydro form by DHFR to be useful for intracellular metabolism. Inhibition of DHFR following methotrexate exposure ultimately leads to depletion of intracellular reduced folates. Cessation of first thymidylate and then purine nucleotide synthesis occurs as an indirect effect of methotrexate on reduced-folate levels. Methotrexate metabolites (polyglutamates) may also have direct inhibitory effects on folate-requiring enzymes, e.g., thymidylate synthase [18], and these effects may be important in inducing cytotoxicity.

2.1.1. Mechanism of Action and Mechanisms of Resistance

Transport. At concentrations less than 10 μM, methotrexate and reduced folates enter cells via an energy-dependent, temperature-sensitive carrier mechanism [19]. The affinity for this carrier has been variously reported to fall between 1 and 10 μM for tumor cell lines [19–21] and to be 87 μM for normal intestinal epithelial cells [22]. These differences in efficiency of transport may account for some of the selectivity of methotrexate for neoplastic cells. In addition to this carrier-mediated transport system, there exists a second, low-affinity trans-

port mechanism that is poorly understood but appears to play a role in the transport of drug when concentrations exceed 20 μM [21], [23]. Methotrexate and reduced folates do not compete for uptake by this process, and it may represent a means for drug entry in cells resistant to low doses of drug by virtue of defective transport by the high-affinity mechanism. In some models, the sensitivity of a cell to methotrexate can be directly correlated with efficiency of drug transport, i.e., sensitive cells have a greater capacity for drug transport and longer intracellular retention of drug when compared to methotrexate-resistant cells [24]. Because decreased membrane transport may play a role in clinical drug resistance, a number of analogs with high lipid solubility have been developed that can circumvent a transport deficit. Methotrexate esters, diaminopyrimidines, and triazenates have been synthesized and used with success against experimental cell lines with defective methotrexate transport.

Intracellular Metabolism. Once inside the cell, naturally occurring folates may be metabolized to *polyglutamates;* that is, additional glutamyl moieties are added to the terminal glutamate present on the parent compound. This process allows for selective intracellular retention of the polyglutamated forms and an increased affinity for certain folate-requiring enzymes, such as thymidylate synthase, and for enzymes required for the de novo production of purine nucleotides [25]. Like the naturally occurring folates, intracellular methotrexate is also polyglutamated with the addition of from one to four additional glutamyl residues [26]. This process has been demonstrated in a variety of tissues, including human breast cancer cell lines [26], normal human liver [27], and murine leukemia cells [28]. The polyglutamates of methotrexate are selectively retained by the cells and appear to have an enhanced inhibitory potential for certain enzymes [18]. The inhibitory capacity of methotrexate polyglutamates for dihydrofolate reductase appears to be somewhat greater than that of the parent drug. The selective retention of methotrexate polyglutamates may be critical for the delayed cytotoxicity exhibited by cells capable of polyglutamate synthesis. In vitro experiments using MCF-7 human breast cancer cells have demonstrated that the intracellular retention and duration of binding to dihydrofolate reductase are directly related to the length of the polyglutamate tail [29].

Interaction with Dihydrofolate Reductase. The binding of methotrexate to dihydrofolate reductase has been extensively investigated by X-ray crystallographic and amino acid sequencing studies [30–34]. Methotrexate binds in a stoichiometric fashion to a hydrophobic pocket in the target enzyme DHFR [35]. The binding affinity depends on multiple factors, including pH, salt concentration, and NADPH concentration, and has been reported to be ca. 10 pM [36]. In the cell, methotrexate is a reversible inhibitor capable of being displaced by high concentrations of substrate. Thus, free intracellular drug in excess of the cellular dihydrofolate reductase binding capacity is required to maintain complete inhibition of the enzyme and thereby produce and maintain a state of reduced-folate depletion. If an excess of intracellular drug is not maintained, the intracellular reduced-folate pool recovers through enzymatic reduction of oxidized folates and cellular metabolism resumes.

Cellular resistance to methotrexate has been most commonly associated with an increase in dihydrofolate reductase activity. In general, the amplified enzyme is identical to the native protein in its affinity for methotrexate; however, altered methotrexate affinity has been reported to correlate with sensitivity to methotrexate in a series of murine leukemias [36]. Increased reductase activity and resistance to methotrexate has also been demonstrated in a number of cell lines made resistant in vitro by stepwise increases in drug concentration [37], [38], and in human tumor samples from clinically resistant tumors [39]. The increased enzyme levels can be correlated to gene amplification that may take the form of small new pieces of chromosomal material, called double minutes, or of large chromosomes, referred to as homogeneously staining regions (HSRs). The former variety of amplification imparts relatively unstable resistance, which requires the ongoing selective pressure of drug presence to be maintained [40], whereas the HSRs represent a more durable form of amplification and thus resistance. Several investigators [41–43] have successfully transvected amplified reductase genes into normal hematopoietic cells, allowing greater marrow resistance to metho-

trexate, an important dose-limiting toxicity of the drug.

Determinants of Cytotoxicity. Methotrexate is an S-phase-specific agent whose cytotoxic effects are determined by drug concentration and duration of cell exposure. These effects may be altered by the cellular milieu. The toxic effects of methotrexate can be completely reversed by exogenous administration of the end products (purines and thymidine) whose de novo synthesis is inhibited by methotrexate treatment. Also, the synthesis of these products may resume if an exogenous source of reduced folates is provided. These data provide the rationale for the treatment of patients with high-dose methotrexate and subsequent administration of a reduced folate in the form of leucovorin calcium (N^5-formyl tetrahydrofolic acid) as "rescue." The reversal of methotrexate cytotoxicity by reduced folates is a competitive process. The reasons for the competitive nature of this relationship are unclear but may be the result of a shared membrane transport system. In addition, methotrexate may have direct inhibitory effects on enzymes other than dihydrofolate reductase that require competitive levels of the folate cosubstrate to overcome the inhibition.

2.1.2. Analogs

Many new analogs to methotrexate have been developed in an effort to circumvent the cellular resistance that occurs with prolonged methotrexate exposure. As mentioned, drugs with increased lipid solubility have been successful in treating transport-resistant cells in vitro [44]. The lipophilic derivative metoprine and variations of the 10-deazaaminopterin series are the most interesting additions. Of the 10-deaza series, an ethyl sub-stitution at the 10-position imparts a marked increase in cytotoxicity when compared to methotrexate [45]. The analog possesses an improved membrane transport ability while retaining a high affinity for dihydrofolate reductase. A new antineoplastic agent is piritrexim isothionate [*79483-69-5*], 6-[(2,5-dimethoxyphenyl)methyl]-5-methylpyrido[2,3-d]pyrimidine-2,4-diamine mono-2-hydroxyethanesulfonate, $C_{17}H_{19}N_5O_2$ [46], that inhibits dihydrofolate reductase (DHFR). Further lipophilic DHFR-inhibitors are trimetrexate [*82952-645*] [47], and edatrexate [48] which are clinically studied and have shown activity, e.g., in non-small cell lung cancer. Thymidylate synthase (TS) is the rate-limiting enzyme in the anabolism of thymidine resulting in the incorporation into DNA. Raltitrexed (company codes: ZN-1694, D-1694, ICI-D1694) [*112887-68-0*] [49], is currently under clinical investigation with response rates in colon and breast cancers of up to 30 % [50], [51]. Myelosuppression seems to be the predominant dose limiting toxicity.

Piritrexim

Raltitrexed

Trimetrexate

AG 331

Edatrexate

Crystallographic data and computer-assisted drug design led to the development of thymidylate synthase (TS) inhibitors of the type of AG 331 [52].

Finally, CB 3717, a potent inhibitor of thymidylate synthase, is toxic for cell lines with altered dihydrofolate reductase; and homofolate, a de novo purine inhibitor requiring di-

hydrofolate reductase for activation, is effective in reductase-amplified lines [44].

2.2. Fluoropyrimidines

5-Fluorouracil (NSC-19893) [*51-21-8*], 5-fluoro-2,4-(1*H*, 3*H*)-pyrimidinedione, 5-FU, $C_4H_3FN_2O_2$, M_r 130.08, is a fluorinated pyrimidine whose structural formula resembles thymine; the hydrogen in the 5-position of the naturally occurring pyrimidine being replaced by fluorine. The *synthesis* of 5-FU in 1957 [15] represents the first successful effort in the rational design of anticancer drugs [53], and was predicated on the earlier observation that malignant cells selectively utilized uracil (and possibly toxic uracil analogs) in vivo [16], [54].

5-Fluorouracil

5-FUDR

Since the original synthesis of 5-FU and its nucleoside 5-FUDR (NSC-27640) [*50-91-9*], 2′-deoxy-5-fluorouridine, floxuridine, $C_9H_{11}FN_2O_5$, M_r 246.21, much has been learned about the mechanism of action of the fluoropyrimidines. These drugs are useful in the treatment of a wide range of human malignancies.

2.2.1. Mechanism of Action

Both 5-FU and 5-FUDR are prodrugs that require intracellular metabolism to their respective nucleotides for cytotoxicity. The pathways for fluoropyrimidine activation are shown in Figure 1. Each drug is enzymatically activated by different routes to FdUMP, FUMP, or FUTP, and each of these fluorinated nucleosides has different mechanisms of cytotoxicity.

Thymidine phosphorylase converts 5-FU to the deoxyribonucleotide 5-FUDR, which is then phosphorylated by thymidine kinase to yield 5-FdUMP. In the presence of methylene tetrahydrofolate, 5-FdUMP forms a stable ternary complex with thymidylate synthetase (TS), inhibiting this critical enzyme to cause "thymineless death." As expected, cytotoxicity is prevented in the presence of exogenous thymidine in these cells with intact salvage pathways. Inhibition of TS has long been considered the principal mechanism of 5-FU cytotoxicity, but it has also been demonstrated that 5-FU can be converted to 5-FUMP, either by orotic acid phosphoribosyl-transferase (OPRTase) in the presence of phosphoribosyl pyrophosphate (PRPP), or by stepwise conversion to the ribonucleotide 5-FUR (by uridine phosphorylase) followed by formation of 5-FUMP by uridine kinase. This intermediate can be converted to 5-FdUMP by ribonucleotide reductase to inhibit TS. Alternatively, 5-FUMP can be phosphorylated to 5-FUTP, which may be fraudulently incorporated into RNA to induce cytotoxicity. In a number of tumor models, loss of clonogenic capacity is directly correlated with the extent of incorporation of 5-FUTP into RNA [55], [56]. This RNA-specific toxicity is not reversed by thymidine. However, the precise mechanism of RNA-induced cell kill is speculative. The most consistent structural effect of 5-FU exposure is impaired processing of ribosomal RNA [57]. This concept is not supported by current evidence, however, as neither the synthesis nor the translation of messenger RNA (mRNA) appears affected by documented 5-FUTP incorporation into mRNA. Using human colon carcinoma cells propagated in vitro, neither quantitative nor qualitative differences in the translational products (polypeptides) of 5-FUTP-containing mRNA could be demonstrated [58]. However, small nuclear RNA species responsible for exon recognition during RNA splicing do contain significant quantities of uridylic acid [59]. Specific substitution of 5-FUTP into this RNA fraction may be critical for 5-FU toxicity.

As shown in Figure 1, 5-FdUMP can be further phosphorylated to 5-FdUTP, which can be incorporated into tumor cell DNA [60], [61]. This mechanism of drug action has been particularly difficult to appreciate, since the fraudulent base is quickly excised from DNA by the enzymes uracil-DNA glycosylase and dUTP nucleotidohydrolase. Thus, when tumor cells are incubated at low (0.1 μM) concentrations

Figure 1. Pathways for fluoropyrimidine activation

of 5-FUDR, single-strand DNA shifts to lower molecular mass species, suggesting excision of the fluorinated base [62]. However, the actual presence of 5-FdUTP in cellular DNA cannot be detected until tumor cells are exposed to higher drug concentrations. Apparently, the importance of 5-FU incorporation into DNA varies from tumor to tumor, with human promyelocytic leukemia cells incorporating nearly 100-fold more 5-FdUTP into DNA than mouse leukemia cells [63]. The importance of this pathway both to tumor cell cytotoxicity and therapeutic index remains to be elucidated.

2.2.2. Mechanisms of Resistance

Tumor cells selected for in vitro resistance may demonstrate a deletion of critical drug-activating enzymes, including uridine kinase [64], orotic acid phosphoribosyltransferase [65], [66], and uridine phosphorylase [67]. Methylene tetrahydrofolate is required for 5-FdUMP inhibition of TS, and decreased availability of intracellular folates has been involved as a mechanism of 5-FU resistance [68].

In addition, alterations in the target enzyme TS can result in drug resistance. Resistant cells have been described with altered thymidylate synthetase having decreased affinity for FdUMP [69–71]. In addition, increased specific activity of TS has been reported in drug-resistant fibroblasts [72] and tumor cells [73], [74]. Whether elevated levels of target protein represent the end result of specific gene amplification (as has been documented for methotrexate resistance) remains to be determined.

2.2.3. Other Fluoropyrimidines

Attempts to develop fluoropyrimidines with improved therapeutic indexes have resulted in the synthesis and clinical trial of so-called *masked fluoropyrimidines.* The masked fluoropyrimidine 5′-deoxy-5-fluorouridine is a nontoxic prodrug that is converted to 5-FU by pyrimidine nucleoside phosphorylase. Because this enzyme may be present to a greater degree in some tumor cells than in normal human bone marrow, an improved therapeutic index can be demonstrated in vitro using breast, sarcoma, leukemia, and colon carcinoma cells [75]. Since 5′-deoxy-5-fluorouridine requires conversion to 5-FU and is in itself nontoxic, tumor cells that lack phosphorylase activity are resistant to the masked compound, while remaining cross-sensitive to 5-FU [76].

Ftorafur is a second masked fluoropyrimidine that is less myelosuppressive than 5-FU. However, the drug has a higher incidence of gastrointestinal and nervous system toxicity, which is probably due to organ-specific localization of activating enzymes [77]. In early clinical studies, ftorafur has shown antitumor activity in patients with 5-FU refractory colorectal and breast cancer [78].

2.3. 5-Azacytidine

5-Azacytidine (NSC-102816) [*320-67-2*], 4-amino-1-β-D-ribofuranosyl-1,3,5-triazine-2(1*H*)-one, 5-azacitidine, $C_8H_{12}N_4O_5$, M_r 244.21, is a pyrimidine analog that was first isolated as a fermentation product from *Streptoverticillium* cultures [79] and was chemically synthesized in Czechoslovakia in 1964 [80]. Structurally, 5-azacytidine differs from cytidine by the substitution of nitrogen in the 5 position of the pyrimidine nucleus.

5-Azacytidine

2.3.1. Mechanism of Action

5-Azacytidine shares the facilitated transport system for cytidine for entry into cells [81] and must be phosphorylated to exert cytotoxic effects. Conversion to the monophosphate is catalyzed by the enzyme uridine – cytidine kinase [82], and this is likely the rate-limiting step for drug activation [83]. 5-Azacytidine monophosphate inhibits the enzyme orotidylate decarboxylase and interferes with de novo pyrimidine biosynthesis [84]. Subsequent metabolism of the monophosphate to azacytidine di- and triphosphate, catalyzed by cytidine monophosphate kinase and nucleoside diphosphate kinase, occurs rapidly and does not appear to be a rate-limiting step in drug activation [81].

The diphosphate of azacytidine is a substrate for ribonucleotide reductase and dAzaCTP (deoxyribonucleotide triphosphate of azacytidine) for DNA polymerase, allowing direct incorporation of drug into DNA [85]. This pathway may be critical for cytotoxicity because active DNA synthesis correlates with drug sensitivity in vitro [86]. In addition, incorporation of 5-azacytidine into DNA may affect gene expression. Mammalian DNA contains ca. 5 % of incorporated cytosine methylated in the 5 position [87]; methylation appears to inhibit gene expression. Thus the globin gene is hypomethylated in bone marrow as compared to other tissues [88–91]. The DNA containing even low levels of 5-azacytidine is a potent inhibitor of the enzyme responsible for cytosine methylation, i.e., DNA cytosine methyltransferase [92], [93]. The enzyme inhibition is disproportionately great compared with the small amount of incorporated fraudulent base, and appears to result from formation of a stable complex between 5-azacytidine residues and the methyltransferase, similar to the complex formed with thymidylate synthase and FdUMP [94]. Thus, in vitro treatment with 5-azacytidine can induce DNA hypomethylation and differentiation of murine cells [95], [96]. More recently these observations have been extended to clinical medicine. Azacytidine treatment in a patient with severe β-thalassemia could stimulate gamma-globin synthesis by inducing hypomethylation and expression of the gamma-globin gene [97].

After conversion to a triphosphate, azacytidine also competes with CTP for incorporation into RNA [98] and inhibits maturation of ribosomal and transfer RNA [99]. This causes disassembly of polyribosomes [100] and interferes with protein synthesis [101].

2.3.2. Mechanism of Resistance

Cellular resistance to 5-azacytidine may be the result of either decreased drug activation or possibly increased drug degradation. Drug metabolism by cytidine kinase appears to be rate-limiting in drug activation; deletion of this enzyme has been reported in 5-azacytidineresistant cells in vitro [81], [102]. Cytidine deaminase degrades 5-azacytidine to 5-azauridine; however, the role of this enzyme in drug resistance remains uncertain. For example, drug toxicity may be dependent on deamination; bacteria incapable of forming 5-azauridine from 5-azacytidine are resistant to the drug [103].

2.3.3. New Analogs

In clinical trials 5-azacytidine has demonstrated consistent antileukemic activity, inducing complete remissions in a significant number of

heavily pretreated patients with acute myelogenous leukemia [104]. Acute dose-limiting toxicities associated with bolus drug administration (severe gastrointestinal symptoms, fever, life-threatening hypotension) may be ameliorated by administering the drug via constant intravenous infusion [105]. However, 5-azacytidine is chemically unstable, undergoing ring opening at the 5,6-imino double bond to form *N*-formylamidinoribofuranosylguanylurea, which further decomposes to ribofuranosylurea [106]. The halflife of this decomposition is 4 h, complicating the task of strict dosage control of prolonged infusions.

To circumvent the problem of aqueous instability, the hydrolytically susceptible 5,6-imino bond of 5-azacytidine was reduced to produce *dihydro-5-azacytidine* (NSC-264880) [*62402-31-7*], 4-amino-5,6-dihydro-1-β-D-ribofuranosyl-1,3,5-triazine-2(1*H*)one · monohydrochloride, $C_8H_{14}N_4O_5 \cdot HCl$, M_r 282.7 [107]. This compound has completed phase I trials in the 1980s with preliminary evidence of activity in lymphoma; in addition it exhibits the unusual dose-limiting toxicity of chest pain at the maximally tolerated dose [108].

Dihydro-5-azacytidine

2.4. Cytosine Arabinoside (Ara-C)

Ara-C (NSC-63878) [*147-94-4*], 4-amino-1-β-D-arabinofuranosyl-2(1*H*)-pyrimidone, cytarabine, cytosine arabinoside, $C_9H_{13}N_3O_5$, M_r 243.22, an antimetabolite that is a structural analog of cytidine, differs from the physiologic nucleoside by the epimeric configuration of the β-*trans*-hydroxyl group at the 2′ position of the sugar. The drug is transported into cells by a carrier-mediated process with shared affinity for deoxycytidine [109]. Once ara-C has entered the cell, cytotoxicity is dependent on formation of the triphosphate ara-CTP, which is responsible for inhibition of DNA synthesis.

Cytosine arabinoside

The precise *mechanism* by which ara-CTP inhibits DNA synthesis remains uncertain. Ara-CTP does inhibit both DNA polymerase α [110] and β [111]. The former is essential for DNA synthesis, the latter for DNA repair. Ara-CTP can be directly incorporated into DNA as well, and this pathway correlates strongly with cytotoxicity. The extent of drug incorporation into DNA is proportional to cell kill in both acute myelocytic and promyelocytic leukemia cells [112]; incorporation and cytotoxicity can be modulated by thymidine [113]. Also ara-C-substituted DNA is unstable under conditions of alkaline elution, suggesting drug-induced strand fragility and breakage [114]. Ara-CTP incorporation also directly blocks strand elongation [115] and causes premature strand termination [116]. This results in accumulation of DNA peaks of small sizes, suggesting that preexisting DNA may be nicked following exposure to ara-C [117]. A further effect of ara-C exposure is inhibition of DNA repair, as determined by alkaline elution studies in L 1210 cells [118]. As might be expected, cells pretreated with ara-C are more sensitive to ionizing radiation, suggesting potentiation of radiation damage by inhibition of DNA repair [119], [120–123].

2.4.1. Mechanisms of Resistance

A number of mechanisms of resistance to ara-C have been described. Ara-C itself is a prodrug that is metabolized first to ara-CMP by deoxycytidine kinase, then to ara-CDP by pyrimidine nucleoside monophosphate kinase, and finally to ara-CTP by nucleoside diphosphate kinase. Resistant cell lines lack the initial, rate-limiting activating enzyme [115], [124].

Since the 1980s, HPLC has been used to separate and semipurify deoxycytidine kinase, pyrimidine nucleoside monophosphate kinase, and pyrimidine nucleoside diphosphate kinase from cell extracts [125]. In murine leukemia cells selected for ara-C resistance, deoxycytidine kinase was found in lower specific activity, and similar results have been reported for other systems [126].

In addition, expansion of the intracellular pool of the physiologic substrate deoxycytosine triphosphate can inhibit ara-C activation by feedback inhibition of the initial activating enzyme [127]. Moreover, increased dCTP pools may also compete directly with ara-CTP for DNA polymerase. Experiments have shown a relationship between duration of leukemia remission and the ability of tumor cells obtained from patients to form and retain ara-CTP in vitro [128], but the mechanisms underlying this relationship remain to be established.

Although some workers have reported that increased drug catabolism by cytidine deaminase may underlie both de novo and acquired drug resistance in patients with leukemia [129], a definite clinical correlation between response and levels of this enzyme has not been established in several studies [130–132].

2.4.2. New Analogs

Several ara-C analogs have been rationally designed with the goal of overcoming specific mechanisms of resistance. Compounds with lipophilic side chains are relatively resistant to inactivation by cytidine deaminase. Another analog with lipophilic modifications in the side chain is enocitabine (NSC-239336, BHAC) [*055726-47-1*] [133], [134]. N^4-Behenoyl-ara-C (BHAC) has undergone clinical trial in patients with acute leukemia [135]. Despite its lipophilicity, the drug does not enter the cerebrospinal fluid and concentrates in bone marrow and red blood cells. N^4-Palmitoyl-ara-C can be administered orally and appears to be more active than the parent compound in preclinical models [136]. Although developed as an antiviral agent, 2′-fluoro-5-iodo-1-β-D-arabinofuranosylcytosine (FIAC) has significant antitumor activity [137]. Interestingly, this compound may be relatively cytotoxic for cells with high levels of cytidine deaminase because the catabolism product, FIA-uracil, is more toxic than the parent compound [138].

2.5. Deoxycytidine and Analogs

The pyrimidine antimetabolite gemcitabine (LY-188011, dFdC) [*095058-81-4*], 2'-deoxy-2',2'-difluorocytidine, $C_9H_{11}F_2N_3O_4$ is an analog of deoxycytidine and a result of a program initiated at Lilly Research to synthesize fluorinated D-ribose and fluorinated nucleosides [139–142]. The difluorinated analog of cytarabine, gemcitabine was identified as novel antimetabolite with a broad spectrum of antitumor activity.

Trade names: Gemicitabine monohydrochloride [*122111-03-9*] is on the market as Gemzar in the indication of palliative treatment of locally advanced or metastatic non-small cell lung cancer.

Mechanism of Action. Gemcitabine shows good activity against human leukemic cell lines, a number of murine solid tumors, and human tumor xenografts [143–146]. Gemcitabine was significantly more cytotoxic than cytarabine in Chinese hamster ovary cells. The major cellular metabolite is the 5'-triphosphate of gemcitabine. The cytotoxicity was competitively reversed by deoxycytidine, suggesting that the biological activity required phosphorylation by deoxycytidine kinase [145].

Tumor-bearing mice were treated with either gemcitabine or cytarabine (20 mg/kg). DNA synthesis reached 1 % of control levels upon administration of gemcitabine. The greater accumulation of gemcitabine-5'-triphosphate compared with cytarabine-5'-triphosphate may cause greater cytotoxicity and therapeutic activity [146].

Gemcitabine

Further gemcitabine may enhance its own cytotoxic effects by self-potentiation mechanisms

that act on, e. g., deoxycytidine monophosphate deaminase, deoxycytidine kinase or on DNA-synthesis [147], [148].

2.6. 2-Halopurines and Analogs

Cladribine (2-CdA, RWJ-26251) *004291-63-8*, is a purine deoxyribonucleoside with remarkable antileukemic activity. It represents a significant advance over existing therapy because it is given as a single 7-day continuous treatment, thus minimizing the side effects observed with multiple treatments. Remission rates of up to 89 % lasting for up to 25 months were observed in clinical trials in patients with hairy cell leukemia [149–152]. The antimetabolite used for first line treatment of hairy cell leukemia [153].

Trade name: Leustatin.

Fludarabine phosphate (NSC-312887, 2-F-ara-AMP) [*075607-67-9*] [154], 2-fluoro-9-(5-*O*-phosphono-β-D-arabino-furanosyl)-9*H*-purin-6-amine, $C_{10}H_{13}FN_5O_7P$, M_r 365.21, another cytotoxic purine antimetabolite, acts via inhibition of DNA synthesis. The product is used for treatment of patients with chronic lymphocytic leukemia.

Trade names: Fludara (Berlex), Benefluor (Schering AG).

Cladribine

Fludarabine

Mechanism of Action. Fludarabine and its soluble derivatives interfere with phosphorylation, e.g., in L 1210 cells. Fludarabine behaves more like an analog of deoxycytidine than adenine or deoxyadenine as indicated by reports [155] demonstrating that the presence of fluorine in the 2-position of the adenine ring alters its function as a substrate for deaminase and nucleoside kinases. This results in differences in biological activity and metabolism. Halogenation does not simply block deamination, but also influences the enzyme that carries out the phosphorylation, as a result cytotoxicity is increased [156]. Fludarabine phosphate may selectively inhibit the incorporation of thymidine and uridine into the DNA molecule by inhibiting both ribonucleotide reductase [157] and DNA polymerase [158]. The maximum tolerated dose (MTD) in heavily pretreated patients with advanced malignancy/solid tumors on the daily regimen was about 15 mg/m^2. Granulocytopenia and thrombocytopenia were dose-limiting [159–161].

Pentostatin. The cytotoxic and immunosuppressant pentostatin (NSC-218321, CI-825, PD-81565, YK-176, 2-deoxycoformycin, 2'-dCF) [*063677-95-2*], (R)-3-(2-deoxy-β-D-erythro-pentofuranosyl)-3,6,7,8-tetrahydroimidazo[4,5-d][1,3]diazepin-8-ol, $C_{11}H_{16}H_4O_4$, M_r 268.13, *mp* 220 – 225 °C, can be isolated from the fermentation broth of *Streptomyces antibioticus* NRRL 3238 [162], [163] or *Aspergillus nidulanus* Y 176-2 or *Emericella* [164]. The adenosine nucleoside analog pentostatin, is the most potent inhibitor of adenosine deaminase, which is an important and ubiquitous cellular enzyme. The inhibition of this enzyme leads to accumulation of dATP which inhibits ribonucleotide reductase and thus DNA synthesis. Pentostatin was launched for treatment of hairy-cell leukemia refractory to α-interferon.

Trade names: Nipent (Parke-Davis, Lederle), Coforin (Katetsuken).

Pentostatin

Mechanism of Action. The highest activity of adenosine deaminase is found in lymphoid tissue as well as in the malignant cells of acute lymphoblastic leukemia [165]. Since pentostatin is the most potent inhibitor of adenosine deaminase it was expected to possess antitumor properties against certain malignancies, especially acute leukemias, chronic myelogenous leukemia, and lymphomas. Surprisingly, when tested against murine tumor models and also against various tumor cell cultures no antitumor effect was found [166]. However, in a phase I clinical trial the compound was found to produce a drop in lymphoblast count and showed antitumor activity in acute leukemia and lymphoma. The toxicity observed consisted mostly of CNS side effects including nausea, hepatic and renal dysfunction. In combination with vidarabin (Ara-A) (→ Chemotherapeutics, Chap. 4.6.1.) superiority to monotherapy was demonstrated in various studies [167], [168]. Durable complete remission was observed after pentostatin treatment in patients with hairycell leukemia resistant to α-interferon [169–174].

2.7. 6-Mercaptopurine and 6-Thioguanine

The purine antimetabolites, 6-mercaptopurine (NSC-755) [*50-44-2*], 1,7-dihydro-6*H*-purine-6-thione, 6-MP, $C_5H_4N_4S$, M_r 152.19; and 6-thioguanine (NSC-63878) [*154-42-7*], 2-amino-1,7-dihydro-6*H*-purine-6-thione, 6-TG, $C_5H_5N_5S$, M_r 167.21, have been used for several decades in the treatment of leukemia and certain other neoplastic diseases. The 6-thiopurine analog, 6-MP, was first synthesized in 1952 [175]; subsequently the same workers synthesized 6-TG in 1955 [176]. The clinical evaluation of 6-MP in the treatment of acute leukemia and chronic myelocytic leukemia was carefully studied in 1953 [177]. Shortly thereafter, the 2-amino analog of 6-MP, 6-TG, was submitted for clinical evaluation as an antitumor agent [178].

R = H, 6-Mercaptopurine
R = NH_2, Thioguanine

6-Mercaptopurine is used for maintenance therapy of acute lymphocytic and acute myelogenous leukemia, and 6-TG is used primarily for remission induction in acute myelogenous leukemia. Although 6-MP and 6-TG have an important role in chemotherapy of leukemia patients, the purine analogs produce low-response rates in patients with solid tumors, lymphomas, and chronic lymphocytic leukemia.

2.7.1. Mechanism of Action

6-Mercaptopurine has been used as an antineoplastic and immunosuppressive agent for decades, but the precise mechanism by which it exerts its cytotoxic effects has not yet been established. Both 6-MP and 6-TG must be converted to their thiol nucleotide form, which is the active cytotoxic moiety. The conversion is catalyzed by hypoxanthine guanine phosphoribosyltransferase (HGPRT) [179–181] and the reaction is dependent on the phosphoribosylpyrophosphate (PRPP) level in the cells [182–186]. 6-Thiouric acid (6-TU) is the major catabolic product of 6-MP. The rapid conversion of 6-MP to 6-TU by xanthine oxidase [187], [188] in leukemic cells may be a possible mechanism of 6-MP resistance [182], [189], [190]. The antineoplastic effect of 6-TG is similar to that of 6-MP. In its nucleotide form, 6-TG inhibits de novo purine biosynthesis and purine interconversions [191–195].

The cytotoxicity of 6-MP and 6-TG has been linked to (1) the interference with de novo purine biosynthesis and purine interconversions, (2) the inhibition of in vitro RNA synthesis, and (3) the incorporation into DNA during S phase, resulting in a deformation of the DNA.

The interference with de novo purine biosynthesis by 6-MP is regulated by 6-MP nucleotides. These nucleotides inhibit the enzyme 5-phosphoribosylpyrophosphate amidotransferase that catalyzes the initial reaction in the purine biosynthetic pathway [196]. The 6-MP nucleotides also inhibit conversion of inosine monophosphate (IMP) to adenine monophosphate (AMP) and to xanthine monophosphate (XMP), and limit the availability of XMP to form guanine monophosphate (GMP), thereby interfering with the sup-

ply of purine precursors for nucleic acid synthesis [181]. In the 1980s two new findings pertaining to the cytotoxicity mechanism in tumor cells have been reported. Studies of human lymphoma revealed that 6-MP was a potent inhibitor of cellular RNA synthesis and that 6-thioITP inhibited both the RNA polymerase I and RNA polymerase II activities of these cells [197]. These data suggested that direct inhibition of the enzymes mediating transcription by 6-thio-IMP may be one of the mechanisms for the cytotoxic action of 6-MP in human tumor cells. Using 6-TG as a cytotoxic agent resulted in severe chromosome damage in wild-type CHO cells [198]. Gross unilateral chromatid damage resulted, and the unilateral nature of this damage was probably due to malfunction of 6-TG-containing DNA as a replication template.

2.7.2. Mechanism of Resistance

Several mechanisms of resistance to these agents have been described in experimental tumors and relate to the pathways of antimetabolite activation and degradation. A decreased HGPRT activity in tumor cells diminishes antimetabolite activation, and this resistance pathway has been reported by several workers [199–202]. However, the HGPRT-regulated mechanism as a basis for drug resistance in human leukemic cells is relatively uncommon [203]. The resistance of 6-MP is related to an increase in alkaline phosphatase in sarcoma cells [204]. Increased alkaline phosphatase, a membrane-bound enzyme that converts the active mononucleotide to 6-thioinosine and inorganic phosphate, has also been reported in human leukemia patients resistant to drug treatment [205], [206]. Another enzyme in the degradation pathway of 6-MP that needs to be considered for drug efficacy and bioavailability is xanthine oxidase, which is responsible for converting 6-MP to 8-OH-6-MP and subsequently to thiouric acid, which is excreted through the urine.

To understand further the bioavailability and pharmacokinetics of thiopurines, the effect of allopurinol on 6-MP catabolism was studied. Allopurinol, an analog of hypoxanthine, enhances the therapeutic efficacy of 6-MP by inhibiting xanthine oxidase. The urinary excretion of 6-MP metabolites is markedly reduced in patients treated with allopurinol. Furthermore, allopurinol increased the plasma level of 6-MP in rabbits [207]. The data suggest that inhibition of 6-MP catabolism by allopurinol may contribute to a greater availability of 6-MP to tissues. Studies of the effect of allopurinol on the kinetics of oral and intravenous 6-MP in Rhesus monkeys and in humans demonstrated that allopurinol pretreatment resulted in a nearly 400 % increase in peak plasma concentration of 6-MP in monkeys and a 500 % increase in humans, but only when 6-MP was administered orally [208]. Allopurinol pretreatment had no effect on the kinetics of intravenously administered 6-MP. This difference is due to the action of allopurinol on liver or intestinal xanthine oxidase and inhibition of first-pass metabolism of oral 6-MP. This finding may explain the low and variable plasma levels of mercaptopurine in patients with acute lymphoblastic leukemia treated with oral 6-MP [209]. Although these studies emphasize the catabolic pathway for purines, all the purine and pyrimidine metabolic enzymes may be important to the bioavailability and activation of antimetabolites.

To clarify the mechanisms of resistance to thiopurines and potential drug interactions in tumor cells, studies have focused on the thiopurine-resistant cell lines deficient in HGPRT (L 1210) and the regulation of PRPP formation in thiopurine-resistant cell lines.

The thiopurines are inactive in the base form and must be converted to their respective nucleotides. This activation step requires PRPP as the cofactor and HGPRT as the enzyme to catalyze the conversion to nucleotide. A major biochemical effect of methotrexate is the suppression of purine biosynthesis and expansion of the PRPP pool. Studies of the cytotoxic and biochemical interaction of methotrexate and 6-TG in L 1210 mouse leukemia cells demonstrated that methotrexate can markedly enhance 6-TG activity [210]. Preexposure of cells to methotrexate resulted in a large increase in cytotoxic potency of 6-TG, whereas simultaneous exposure caused an antagonism of 6-TG cytotoxic activity. Although PRPP pools were not measured quantitatively, the effect of methotrexate preexposure was to increase PRPP pools, enhance the activation of 6-TG to 6-TG monophosphate, and thereby increase its incorporation into RNA.

2.7.3. New Analogs

Alkyl disulfide derivatives have been used as masked compounds of 6-mercaptopurines. The antitumor effect of these derivatives has been measured by their ability to decrease the degradation of 6-MP monophosphate. Of the seven 6-alkyl disulfide derivatives of 6-MP and 6-TG in L 1210 leukemia cells tested, decyl derivatives of both 6-MP and 6-TG were the most effective with therapeutic ratios as high as 50 and 48, while those of parent compounds were 6.2 and 5.0, respectively [211]. Partial circumvention of thiopurine resistance may have resulted from cellular uptake of intact acylated bis(6-MP-9-β-D-ribofuranoside-5′)pyrophosphate derivatives in 6-MP-resistant human cell lines deficient in HGPRT (L 1210) [212].

The 6-MP-resistant sublines of P 388 and L 1210 leukemia are also sensitive to two new *purine antagonists:* 5-carbamoyl-1*H*-imidazol-4-yl piperonylate and 4-carbamoylimidazolium-5-olate [213]. These two new purine analogs kill 6-MP-resistant cells by suppressive de novo purine synthesis. The activation of those new purine analogs is mediated by adenine phosphoribosyltransferase.

3. Alkylating Agents

Historically, alkylating agents were important in the early development of cancer chemotherapies. Victims of sulfur mustard gas exposure in World War I were found to have severe lymphoid aplasia as well as pulmonary irritation [214]. This led to clinical trials of the related, but less toxic, nitrogen mustard derivative, which produced tumor regressions in lymphoma patients [215].

Clinical use of nitrogen mustard today is mostly limited to the treatment of lymphomas, especially Hodgkin's disease, where it is used in a multidrug regimen called MOPP (nitrogen mustard, vincristine, procarbazine, and prednisone). Three widely used derivatives of nitrogen mustard used in patients with malignancies today include melphalan, cyclophosphamide, and chlorambucil (Sections 3.2, 3.3, 3.4).

The mechanism by which alkylating agents act can be classified as either S_N1 or S_N2. In the *S_N1 reaction,* a highly reactive intermediate forms initially and quickly reacts with a nucleophile to produce an alkylated product. This reaction follows first-order kinetics because the rate-limiting step is formation of the intermediate. The *S_N2 reaction* is a second-order reaction and thus is dependent on the concentration of both the alkylating agent and its target nucleophile [216]. In general, alkylating agents that react by an S_N1 mechanism, such as nitrogen mustard, are less selective in their reactions than S_N2 agents, but this rule is not always true. Selectivity also depends upon membrane permeability, charge, and reactivity of the drug.

3.1. Nitrogen Mustard

3.1.1. Mechanism of Action

Nitrogen mustard (NSC-762) [*51-75-2*], mechloroethamine, HN2, $CH_3N(CH_2CH_2Cl)_2$, $C_5H_{11}Cl_2N$, M_r 156.07, is activated through loss of one of its chlorines. The α carbon then reacts with the nucleophilic nitrogen to form the positively charged, highly reactive, cyclic aziridinium compound, which is attacked by nucleophiles to give the initial alkylated product. The second chlorine can also leave, initiating a second alkylation, which produces a cross-linked alkylation between two nucleophiles.

Because HN2 bonds covalently to many biologic molecules, such as DNA, RNA, and proteins, the alkylated sites responsible for its cytotoxicity are difficult to determine. However, studies have shown that cytotoxicity is likely to result from inhibition of DNA synthesis by damaging the DNA template [217–219]. The DNA molecule is rich in potential sites for alkylation, including the phosphate groups in the sugar phosphate backbone structure, and the oxygen and nitrogen sites in the purine and pyrimidine bases. However, the tendency for alkylation to occur in the N-7 position of guanine is enhanced. This may be mediated by the increased nucleophilic characteristics of the N-7 deoxyguanosine due to base stacking and charge transfer [220]. Other preferred sites of alkylation in decreasing order are the N-1 of adenosine, the N-3 of cytidine, and the N-3 of thymidine [221].

Bifunctional alkylating agents, such as HN2, produce intra- and interstrand cross-linking bet-

ween DNA in the double-helix structure preferentially at the N-7 guanosine site. Thus, these bifunctional compounds are more effective antitumor agents than their monofunctional analogs; however, increasing the number of alkylating sites on the agent beyond two does not appear to increase antitumor activity [222]. This evidence suggests that DNA cross-linking is critical for alkylator activity. Further evidence for the importance of cross – linking to cytotoxicity comes from alkaline elution studies that can detect low levels of cross-linking in cells exposed to minimal doses of bifunctional alkylating agents [223].

In contrast, monofunctional agents, such as procarbazine and dacarbazine, do not produce DNA interstrand cross-links and appear to exert toxicity by producing single-strand DNA breaks. The increased carcinogenicity seen with some monofunctional alkylating agents may be due to incorrect base pair substitution by DNA repair enzymes that could result in malignant transformation.

3.1.2. Mechanisms of Drug Resistance

Several mechanisms have been elucidated for nitrogen mustard and other bifunctional alkylating agents. First, resistant cells with defective drug transport have been described. Nitrogen mustard enters cells by an active transport system that is physiologically utilized for choline transport. Lymphoma cells resistant to nitrogen mustard demonstrate decreased drug uptake by this specific active transport site, which also decreases its uptake of choline [224]. Second, cytosolic increase in nonprotein sulfhydryl levels [225] and higher nonprotein-bound thiol compounds that could inactivate the drugs before they reach the nucleus have been found in nitrogen mustard-resistant cells [226]. Third, enhanced repair of DNA cross-linking by repair enzymes has been demonstrated in vitro [227] and in vivo [228].

3.2. Melphalan

Melphalan (NSC-8806) [*148-82-3*], 4-[bis(2-chloroethyl)amino]-L-phenylalanine, L-phenylalanine mustard, $C_{13}H_{18}Cl_2N_2O_2$, M_r 305.20, was rationally designed and synthesized as a phenylalanine derivative of nitrogen mustard with the aim of obtaining increased specificity against melanoma tumor cells that utilize phenylalanine or tyrosine to produce melanin.

Melphalan

Although this compound does not exhibit specific antimelanoma activity, it has a broad-spectrum cytotoxicity in multiple myeloma, breast cancer, and lymphomas.

3.2.1. Mechanism of Action

Melphalan is a bifunctional alkylating agent but differs from HN2 mainly by the presence of an aromatic ring. This ring reduces the nucleophilicity of the nitrogen atom by withdrawing electrons, making the drug less reactive. Thus, it can be taken orally. It retains its alkylating activity but is more selective than nitrogen mustard because it is less likely to form the unstable and highly reactive aziridine intermediate indiscriminately. Like nitrogen mustard, it forms DNA cross-links that are critical for cytotoxic effect. Its cellular uptake is also mediated by an active, energy-dependent transport mechanism shared with leucine and glutamine uptake [218]. Thus, high concentrations of leucine or glutamine can reduce the cytotoxicity of melphalan in a marrow colony-forming unit assay [229]. Another transport mechanism, although less active, can be used by melphalan, and this mechanism is shared by the neutral amino acids alanine, cysteine, and serine [218].

3.2.2. Mechanism of Resistance

Decreased transport of melphalan into drug-resistant leukemia cells has been demonstrated and correlated to the melphalan-resistant phenotype. Specifically, a mutation in the higher velocity transport system has been suggested that results in a decreased affinity of the carrier protein for melphalan and leucine [230]. Evidence

for the other two mechanisms of resistance seen with nitrogen mustard, i.e., increased intracellular thiol compounds and increased DNA cross-linking repair also, exists.

3.3. Cyclophosphamide

Cyclophosphamide (NSC-26271) [*50-18-0*], *N,N*-bis(2-chloroethyl)tetrahydro-2*H*-1,3,2-oxazaphosphorin-2-amine 2-oxide, $C_7H_{15}Cl_2N_2O_2P$, M_r 261.10.

Cyclophosphamide

This widely used bifunctional, cyclic alkylating agent has important clinical use in lymphomas, leukemias, sarcomas, carcinomas of breast and ovary, as well as childhood malignancies. The compound was rationally designed based on data that tumor cells possess high concentrations of enzymes capable of cleaving the P−N bond. This reaction would activate drug by release of the potent antitumor agent phosphoramide mustard. Cyclophosphamide requires hepatic activation by oxidase enzymes. First, it is metabolized by liver microsomes to hydroxycyclophosphamide, which is spontaneously tautomerized to aldophosphamide. Aldophosphamide reaches peripheral tissues and tumors where it is hydrolyzed to yield the active antitumor agent phosphoramide mustard and acrolein. Acrolein has very weak antitumor activity and, when concentrated within the bladder by excretion, can cause hemorrhagic cystitis [216].

3.3.1. Mechanism of Action

Phosphoramide mustard can undergo similar bifunctional alkylation as nitrogen mustard. Also, because of its need for metabolic conversion for biologic activity, cyclophosphamide can be given orally or intravenously.

3.3.2. Mechanism of Resistance

Similar mechanisms of resistance occur for cyclophosphamide as for nitrogen mustard. Also, defective metabolic conversion by the hepatic microsomal system could serve to decrease the bioavailability of aldophosphamide to tumor tissue, but it is not known whether this is significant.

3.4. Chlorambucil

Chlorambucil (NSC-3088) [*305-03-3*], 4-[bis(2-chloroethyl)amino]benzenebutanoic acid, $C_{14}H_{19}Cl_2NO_2$, M_r 304.23. This drug is a close congener of melphalan and exhibits similar stability because of the electron-withdrawing properties of the aromatic ring. It is given orally and has proven efficacy in treating chronic lymphocytic leukemias, multiple myeloma, and lymphomas.

Chlorambucil is thought to have activation properties and mechanisms of resistance similar to melphalan.

Chlorambucil

3.5. Thio-TEPA

Triethylenethiophosphoramide (NSC-6396) [*52-24-4*], 1,1′,1″-phosphinothioylidynetrisaziridine, thio-TEPA, $C_6H_{12}N_3PS$, M_r 189.23. This agent is representative of alkylating agents that have two or more aziridine rings. It has clinical activity against the same tumors as nitrogen mustard and has been used clinically in carcinomas of the breast and ovary. Thio-TEPA is also indicated for intrathecal therapy of meningeal carcinomas. The reactivity of the aziridine groups is increased by protonation; thus thio-TEPA is most active at low pH and has been used to cause sclerosis of malignant pleural effusions that often have an acidic pH.

Thio-TEPA

The mechanisms of action and resistance are similar to those of nitrogen mustard.

3.6. Ifosfamide

Ifosfamide, or isofosphamide (NSC-109724) [*3778-73-2*], *N*,3-bis(2-chloroethyl)-tetrahydro-2*H*-1,3,2-oxazaphosphorin-2-amine 2-oxide, $C_7H_{15}Cl_2N_2O_2P$, M_r 261.07, is an analog of cyclophosphamide [231]. It has approximately one-third the alkylating activity of cyclophosphamide and requires hepatic microsomal conversion to its active form. Also, the rates of conversion by metabolism are similar in both drugs, but less biologically active alkylating moieties are formed in ifosfamide [232]. It has shown promising results in refractory pediatric bone and soft tissue sarcomas, refractory testicular tumors, and Wilms' tumor in children [233], [235].

Trade names: Ifex, Holoxan (ASTA Medica)

Ifosfamide

3.7. Estramustine

Estramustine

From the numerous analogs few found a way into the clinic or to the market. However, estramustine [*489-15-0*] was successfully launched for treatment of prostate cancer [234].

Trade name: Estracyt (Pharmacia/Upjohn)

3.8. Nitrosoureas

The clinically useful nitrosoureas include carmustine (NSC-409962) [*154-93-8*], *N,N′*-bis(2-chloroethyl)-*N*-nitrosourea, BCNU,$C_5H_9Cl_2N_3O_2$, M_r 214.04; lomustine (NSC-79037) [*13010-47-4*], *N*-(2-chloroethyl)-*N′*-cyclohexyl-*N*-nitrosourea, CCNU, $C_9H_{16}ClN_3O_2$, M_r 233.69; methylcyclohexylchloroethylnitrosourea (NSC-94941) [*52662-76-7*], 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea, methyl-CCNU, $C_{10}H_{18}ClN_3O_2$, M_r 248; streptozotocin (NSC-85998) [*18883-66-4*], 2-deoxy-2{[(methylnitrosoamino)carbonyl]amino}-D-glucopyranose, $C_8H_{15}N_3O_7$, M_r 265.22; and chlorozotocin (NSC-178248) [*54749-90-5*], 2-({[(2-chloroethyl)nitrosoamino]carbonyl}amino)-2-deoxy-D-glucose, DCNU, $C_9H_{16}ClN_3O_7$, M_r 313.69. Streptozotocin is a naturally occurring nitrosourea derived from *Streptomyces acromogenes.*

This group of agents was developed by careful structure – function studies based on the antitumor activity of methyl-CCNU [235–237]. The chloroethyl derivatives were found to possess increased activity and a capacity to cross the blood – brain barrier because of their lipophilic nature. Each of these agents is capable of undergoing alkylating reactions with biologic molecules in a manner similar to the classic mustards through the formation of highly reactive chloroethyl carbocations. With BCNU, each molecule of drug may undergo two such reactions to produce nucleic acid strand breaks, and DNA – DNA and DNA – protein cross-links

[238]. Monofunctional CCNU and methyl-CCNU cross-link by initial carbocation formation and alkylation followed by loss of the chloride substituent and formation of a second reactive carbocation. These alkylation reactions appear to be the major mode of cytotoxicity for these agents [239], [240]. With the exception of chlorozotocin, the nitrosoureas may also form an isocyanate compound that may play a role in the toxic side effects of these agents [241], [242], but has little importance in the antitumor effect. In support of this view is the fact that chlorozotocin retains its potent cytotoxic capacity while producing little or no isocyanate compound and reportedly has less marrow toxicity. Experimental evidence raises additional questions concerning the role of isocyanates, which may enhance the antitumor activity of these compounds. Methylnitrosourea, which cannot alkylate DNA to produce cross-linking, produces alterations of nuclear protein in a manner similar to BCNU, and isocyanates are considered a possible explanation for these effects from both agents [243]. Also, sensitivity of a Walker tumor line made resistant to bifunctional alkylating agents can be restored by simultaneous treatment with an isocyanate-producing agent [244].

3.8.1. Mechanism of Action

Because of their lipophilicity, nitrosoureas enter cells by passive diffusion as opposed to an active transport mechanism common to the classic alkylating agents [245]. Once inside the cell, alkylating agent exposure results in pancellular covalent binding of drug to proteins, nucleic acids, and to a variety of smaller intracellular molecules. Which of these reactions is critical for cytotoxicity remains uncertain, but the majority of evidence points to interaction directly with DNA as the focal point of cytotoxicity [246–248]. The 7 position of guanine is particularly susceptible to alkylation, and accounts for the majority of the total alkylation of DNA [249], [250]. Since the chloroethyl nitrosoureas are each capable of two independent alkylations [238], DNA can be cross-linked by either interstrand or intrastrand processes [251]. Multiple studies using a variety of alkylating agents have confirmed that DNA cross-linking, which leads to inactivation of the DNA template, may well be the key mechanism of cytotoxicity [252–254]. Monofunctional DNA alkylations also occur following nitrosourea exposure and these must also be considered cytotoxic as monofunctional alkylating agents, incapable of cross-linking, retain cytotoxic activity. Monofunctional alkylations may produce single-strand DNA breaks by endonuclease cleavage at apurinic sites produced by the alkylation and repair process [255].

3.8.2. Mechanisms of Resistance

The mechanisms of cellular resistance to nitrosoureas remain unclear, although defective drug transport, as has been demonstrated for the classic alkylating agents, would be unlikely given the lack of need for an active membrane transport system. In human glioblastoma cells, increased activity of a specific excision enzyme, guanine-O^6-alkyltransferase, is correlated with in vitro resistance to nitrosoureas [256], and repair mechanisms would seem a likely mechanism since mammalian cells are capable generally of such repair [257].

3.8.3. Analogs

New agents have been synthesized that contain a sugar moiety similar to streptozotocin. Analogs that contain mannose, glucose, ribose, maltose, and galactose have all been produced, with the maltosyl derivative being exceptionally active in a variety of tumors tested [258], [259]. Sugar alcohols, such as mannitol, linked to nitrosoureas retain their cytotoxicity but appear to protect against the marrow toxicity induced by the parent nitrosourea compounds. A number of derivatives with di- and tripeptides containing alkyl nitrosoureas have also been introduced but have met with only moderate preclinical success [260].

There is continuous effort to obtain new nitrosoureas with higher efficiency and/or lower toxicity and several new compounds are undergoing clinical trials. In 1987 ranimustine (NSC-270561, MCNU) [*058994-96-0*], was marketed as Cymerin (Tokyo Tanabe) [261].

The phosphonoalanine derivative fotemustine (S-10036) [*092118-27-9*],

(±)-diethyl[1-[3-(2-chloroethyl)-3-nitroso-ureido]ethyl]phosphonate, $C_9H_{19}ClN_3O_5P$, M_r 315.69, *mp* 85 °C was approved as Muphoran (Servier) for treatment of disseminated malignant melanoma [262], [263]. Side effects of the related compound BCNU (carmustine) have been linked to the inhibitory effect on a major enzyme of the glutathione pathway, the cytosolic glutathione reductase. Fotemustine has no inhibitory effect on cytosolic glutathione reductase, indicating that fotemustine has a lower toxicity than carmustine [264–266]. In addition it has been shown to have lower mutagenicity in the Ames and micronucleus tests compared to BCNU [267]. In the clinical studies the major toxic effects of fotemustine were thrombocytopenia and leukopenia, which were delayed and reversible, nausea and vomiting being mild [268].

Ranimustine

Fotemustine

3.9. Procarbazine

Procarbazine (NSC-77213) [*671-16-9*], *N*-(1-methylethyl)-4-[(2-methylhydrazino)methyl]-benzamide, $C_{12}H_{19}N_3O$, M_r 221.30, is one of a number of substituted hydrazine compounds originally synthesized as monoamine oxidase inhibitors in the early 1960s [269], and found to possess antineoplastic activity, particularly in the treatment of Hodgkin's disease [270]. Procarbazine is nontoxic as the parent compound but undergoes rapid chemical and metabolic degradation to intermediate products that, through a variety of mechanisms, are capable of cytotoxicity [271].

A crucial step in the activation of procarbazine appears to be the production of the azo analog *N*-isopropyl-α-(2-methyldiazeno)-*p*-toluamide, which is catalyzed by hepatic microsomal cytochrome P450 [272], [273]. Further metabolism by hepatic microsomes leads to the production of methyl- and benzyl-azoxy metabolites [272], [273]. Cytotoxic alkylating compounds may be formed from these metabolites via hydroxylation reactions, and these may play the major role in cytotoxicity. This sequence of metabolism and formation of the alkylating intermediates is consistent with the time course of appearance of the active species isolated in the serum and then excreted [274], [275]. In addition to the formation of these alkylating intermediates, methyl- and benzyl-azoxy metabolites may result in free radicals through the formation of diazenes [276], which in the presence of oxygen form free radicals and nitrogen. However, free-radical formation is not likely a major cause of cytotoxicity, because drug activity is preserved when cells are exposed to procarbazine under conditions that do not support the formation of free radicals [277]. The degree of toxicity induced by alkylation and by free-radical formation is unknown.

3.9.1. Mechanism of Action

The exact mechanism by which procarbazine produces cytotoxicity is unknown; however, the effects of its action have been well studied at the cellular level. Chromosome breaks and translocations have been demonstrated in vivo in Ehrlich ascites and L 1210 leukemia cells [278]. Inhibition of nucleic acid and protein synthesis and of a variety of enzymes has also been documented following procarbazine treatment. Inhibition of transfer and nuclear RNA synthesis occurs 2 h after procarbazine exposure and lasts for up to 24 h [279]. Thymidine incorporation into DNA is inhibited concomitantly with protein synthesis, reaching maximum inhibition in 12 – 16 h [271], [280]. Although many potentially cytotoxic events have been associated with procarbazine administration, it is not clear which of these effects causes cell death.

3.9.2. Mechanisms of Resistance

Resistance mechanisms for procarbazine are poorly understood, and no detailed studies have been reported that illustrate the typical cellular resistance encountered with alkylating agents. Since the drug enters cells by simple diffusion, resistance is unlikely to involve altered transport mechanisms [281]. New pieces of chromosomal material were found in Ehrlich ascites cells made resistant to procarbazine [271], and these may represent gene amplification, perhaps encoding for a target enzyme or detoxifying enzyme.

3.10. Dacarbazine

Dacarbazine (NSC-45388) [*4342-03-4*], 5-(3,3-dimethyl-1-triazenyl)-1*H*-imidazole-4-carboxamide, DTIC, $C_6H_{10}N_6O$, M_r 182.18, was synthesized in the late 1950s as an analog of 5-aminoimidazole-4-carboxamide, an intermediate in de novo purine synthesis. The drug is a product of rational synthesis, designed as a false intermediate capable of inhibiting de novo purine synthesis. Despite this theoretical basis for antitumor action, DTIC does not function as a purine analog; instead, it is extensively metabolized to a methylating agent [282]. Similar to procarbazine, DTIC must undergo activation by a microsomal oxidase to form a compound that can spontaneously produce a methyl diazonium ion intermediate that is probably the active metabolite. However, more recent evidence suggests a further metabolism to *N*-hydroxymethyl diazonium ion may be responsible for the selective antitumor effect of the drug [283]. Evidence for methylation of nucleic acids has been demonstrated in tissue culture [284]. An additional metabolic pathway involves the light sensitivity of the drug. Exposure to ultraviolet energy converts the parent compound to metabolites with moderate cytotoxicity in vitro [285], but this probably does not represent an important pathway for cytotoxicity in vivo.

Mechanism of Action. The mechanism of action of DTIC has not been systematically investigated, but it appears that the drug may act during any phase of the cell cycle [286] and can produce inhibition of RNA, DNA, and protein synthesis.

3.11. Hexamethylmelamine

Hexamethylmelamine (NSC-13875) [*645-05-6*], *N,N,N′,N′,N″,N″*-hexamethyl-1,3,5-triazine-2,4,6-triamine, altretamine, $C_9H_{18}N_6$, M_r 210.27, was synthesized in 1951 [287]. It has consistent antitumor activity in a variety of solid tumors, including ovarian, lung, and breast cancer.

The compound is almost insoluble in water, and thus, must be administered orally. Neither the mechanism of action nor the products of metabolic breakdown have been firmly established. Following administration of hexamethylmelamine, a spectrum of *N*-demethylation species has been isolated in the urine. The triazine ring appears unaffected by metabolism, as is evident by almost complete recovery of the intact ring in the urine using ring-labeled compound [288]. Existing evidence suggests possible formation of an alkylating species through *N*-demethylation [289] or the formation of *N*-methylol intermediates by hydroxylation of the parent compound [290] to account for the cytotoxic effects of the drug. *N*-Methylol derivatives have cytotoxic effects in vitro, but whether or not these derivatives are formed in vivo is unclear.

Analogs. Pentamethylmelamine (NSC-118742) [*35832-09-8*], *N,N,N′,N′,N″*-pentamethyl-1,3,5-triazine-2,4,6-triamine, $C_8H_{17}N_6$, M_r 196, is the most commonly used analog of hexamethylmelamine and differs by the absence of a single methyl group. Its major advantage is aqueous solubility, allowing an intravenous formulation. Its metabolism, toxicity, and antitumor activity parallel those of hexamethylmelamine [291], [292]. Other metabolites of hexamethylmelamine with varying numbers of methyl groups also possess antitumor activity that, in general, is directly proportional to the number of methyl groups on the triazene ring [292], [293].

3.12. Mitomycin-C

The mitomycins are a family of antibiotics isolated from *Streptomyces caespitosus*.

Mitomycin-C (NSC-26980, MIT-C) [*50-07-7*] [1aR-(1aα,8β,8aα,8bα)]-6-amino-8-[(aminocarbonyl)oxymethyl]-1,1a,2,8,8a,8b-hexahydro-8a-methoxy-5-methylazirino-[2',3':3,4]pyrrolo[1,2-a]indole-4,7-dione, $C_{15}H_{18}N_4O_5$, has DNA-alkylating properties [294]. Mitomycin is applied for treatment of stomach, breast, and gynecological cancers [295], [296]. Dose-limiting are leucopenia and thrombopenia.

Mitomycin

4. Anthracyclines (→ Antibiotics, Chap. 3.2.3.)

Doxorubicin (NSC-123127) [*23214-92-8*], 10-[(3-amino-2,3,6-trideoxy-α-L-lyxo-hexopyranosyl)oxy]-7,8,9,10-tetrahydro-6,8,11-trihydroxy-8-(hydroxyacetyl)-1-methoxy-5,12-naphthacenedione, adriamycin, $C_{27}H_{29}NO_{11}$, M_r 543.54; and daunorubicin (NSC-82151 for HCl salt) [*20830-81-3*], 8-acetyl-10-[(3-amino-2,3,6-trideoxy-α-L-lyxo-hexopyranosyl)oxy]-7,8,9,10-tetrahydro-6,8,11-trihydroxy-1-methoxy-5,12-naphthacenedione, daunomycin, $C_{27}H_{29}NO_{10}$, M_r 527.51. Doxorubicin is used in the treatment of breast cancer, sarcoma, lymphoma, and small-cell lung cancer. Daunorubicin is used more commonly in acute myelocytic and lymphocytic leukemias.

R = $COCH_2OH$, Doxorubicin
R = $COCH_3$, Daunorubicin

Meanwhile epirubicin (4'-epiadriamycin, pidorubicin, IMI-28) [*56420-45-2*], (8S-*cis*)-10-[(3-amino-2,3,6-trideoxy-β-L-arabino-hexopyranosyl)oxy]-7,8,9,10-tetrahydro-6,8,11-trihydroxy-8-(hydroxyacetyl)-1-methoxy-5,12-naphthacenedione, is the most commonly used antineoplastic antibiotic for breast cancer treatment. The total turnover exceeded \$ 200 × 10^6 in 1996. The compound can be synthesized by classical chemical synthesis [297–299].

Trade names: Farmorubicin and Pharmorubicin (Farmitalia).

Epirubicin

In addition idarubicin (NSC-256439, IMI-30, DMDR) [*058957-92-99*] and pirarubicin (THP-ADM) [*072496-41-4*], (8S-*cis*)-10-[[3-amino-2,3,6-trideoxy-4-*O*-(tetrahydro-2H-pyran-2-yl]-α-L-lyxo-hexopyranosyl]oxy]-7,8,9,10-tetrahydro-6,8,11-trihydroxy-8-(hydroxyacetyl)-1-methoxy-5,12-naphthacenedione, $C_{32}H_{37}NO_{12}$, M_r 627,64 are available as idamycin (Adria) and pinorubicin (Nippon Kayaku), respectively.

Idarubicin

Pirarubicin is the 4'-*O*-tetrahydropyranyl analog of adriamycin and can be synthesized from adriamycin [300], [301]. The acute cardiac toxicity was significantly less than that of adri-

amycin and general toxicity lower than that of other analogs [302, 303, 303]. The main indications for pirarubicin are cancer of the bladder, head and neck, and cervix.

Pirarubicin

The anthracyclines are derived from *Streptomyces* species and are structurally tetracyclic chromophore antibiotics [305]. They are classified by their chromophore, otherwise known as aglycone, structure. The sugar most commonly attached to the aglycones is daunosamine, but other sugars may be involved, and these are mentioned in Section 4.3. The basic tetracyclic aglycone structure of the anthracyclines shares many characteristics with the hydroxyanthraquinones, which are ubiquitous in nature.

4.1. Mechanism of Action

DNA–RNA Binding. The exact mechanism of cytotoxicity by anthracyclines is unknown, but they do have multiple and distinct toxic effects that may kill a tumor cell in one or more ways [306].

Initially these drugs were found to bind DNA by intercalation between base pairs perpendicular to the long axis of the double helix, with the major binding occurring between the B and C rings of the drugs with the bases above and below [307]. The daunosamine sugar is thought to bind ionically with the sugar-phosphate backbone of DNA. The binding association constant is between 10^5 and 10^6 M^{-1}. Intercalation of the DNA causes a partial unwinding of the helix and thus disrupts DNA polymerases and transcription. However, these experiments were done with DNA in vitro; DNA in vivo is organized into chromatin, which is DNA wrapped around a series of histone core particles. Also, it has been established that the anthracyclines can affect every DNA function, including initiation, chain elongation, DNA synthesis, DNA repair, and RNA synthesis [308], [309]. Experimentally these compounds can cause sister chromatid exchanges, single- and double-strand breaks, and alkylation of DNA [310], [311]. Interestingly, some results strongly suggest that inhibition of DNA synthesis is not essential for cell kill. New anthracycline analogs, such as aclacinomycin A, which selectively inhibits preribosomal RNA synthesis and not DNA synthesis, retain cytotoxicity. This suggests other non-DNA-mediated mechanisms of cytotoxicity, such as preribosomal RNA synthesis [309].

Free-Radical Generation. Free-radical formation (highly reactive compounds with an unpaired electron) occurs during the metabolism of anthracyclines. When the microsomal enzyme P 450 reductase or xanthine oxidase interacts with and reduces the ketone oxygen in ring B to O^-, a semiquinone radical intermediate is formed. This interacts with oxygen to produce the superoxide radical with regeneration of the original anthracycline structure [312]. The superoxide radical can serve as a substrate for superoxide dismutase to form hydrogen peroxide, which can interact with the superoxide molecules to form hydroxyl radicals [313]. The superoxide and hydroxyl radicals can interact with and damage cells, especially the hydroxyl radical, which is one of the most reactive substances known. Hydroxyl radicals can also react with purine or pyrimidine bases, amines, and thiols. This free-radical formation is responsible for cardiac damage seen with chronic use of the anthracyclines in the treatment of human malignancies. Evidence exists in many animal models, as well as in humans, that superoxide and hydroxyl radical formation occurs in cardiac tissue, leading to lipid peroxidation of mitochondria and sarcosomes [314], [315]. Since mitochondria account for more than 40 % of cardiac muscle mass, as well as being the major source for ATP needed for contraction, and are coupled to calcium release during the action potential, one can easily visualize how these agents mediate cardiac toxicity. However, it now seems apparent that cardiac tissue lacks catalase and that doxorubicin destroys glutathione peroxidase [315], [316]. Agents that can scavenge free-radicals are

under active investigation. Interestingly, there is no evidence to date to link anthracycline free-radical formation to its antitumor activity so that analogs incapable of free-radical formation may demonstrate improved therapeutic index.

Membrane Interactions. Anthracycline binding to cell membranes appears to be an important mechanism for cytotoxicity. Changes in membrane glycoproteins, transmembrane flux of ions, and membrane morphology have been demonstrated in a variety of cells. Doxorubicin binds most tightly to cardiolipin, a phospholipid found in high concentration in mitochondrial and tumor cell membranes but in low concentration in normal cell membranes [317]. Also, membrane redox potential changes occur with drug binding, and may promote free-radical generation. Perhaps the most interesting and important finding to date on this subject is that doxorubicin, covalently linked to beads to prevent cell entry of the drug, retains cytotoxic effects [318]. This suggests that doxorubicin does not need to enter cells or interact with DNA to mediate cell kill.

Another potential mechanism of action may be the dissociation of the cytochrome oxidase electron transport chain for ATP generation [319]. Cytochrome c oxidase requires cardiolipin for activity, and doxorubicin can remove cardiolipin from the enzyme complex, thus inactivating the enzyme.

Metal Ion Chelation. The anthracyclines are capable of chelating ions, including copper, calcium, magnesium, zinc, and iron. Of the metal ions, the tightest complex seems to be with iron(III). Doxorubicin – iron chelates can act as a redox catalyst for electron transfer from glutathione to oxygen, which leads to formation of cytotoxic oxygen radicals. This reaction can also utilize hydrogen peroxide and superoxide, leading to hydroxyl radical formation. Thus, evidence exists that the anthracycline – iron complex can mediate free-radical formation capable of lipid peroxidation and cell damage [320]. Whether this is a mechanism of tumor cell kill is unknown, but the phenomenon may be important to cardiac toxicity.

4.2. Mechanism of Resistance

Probably the most common and important mechanism by which tumor cells become resistant to the anthracyclines is decreased net intracellular accumulation. Many studies have shown that doxorubicin-resistant tumor cells are capable of effluxing the drug more efficiently than their parent sensitive cells [355]. In fact, this mechanism of drug resistance may be responsible for resistance to a variety of structurally unrelated compounds with different modes of antitumor action, such as the vinca alkaloids and actinomycin D. This has been termed pleiotropic drug resistance, and several laboratories have shown the reversal of this resistant phenotype by co-incubation with various calcium channel blockers with doxorubicin [356]. These compounds increase the net intracellular drug accumulation in resistant cells, but the precise mechanism of this action is uncertain.

4.3. Analogs

As mentioned in Section 4.1, anthracycline tumor toxicity is probably related to intercalation with DNA, preribosomal RNA inhibition, and/or membrane binding effects, while cardiac toxicity may be due to free-radical formation by drug and drug – metal complex. Thus, analogs have been developed with less potential for free-radical formation. One such drug in early clinical development is aclacinomycin A (NSC-208734), which has an aklavinone aglycone structure and is derived as a fermentation product of *Streptomyces* [321]. This drug lacks the 11-hydroxyl, and therefore has about 10 % the potential to generate free-radicals in the P 450 reductase system. Although it does not bind DNA as well as doxorubicin, it retains significant antitumor activity.

The National Cancer Institute (USA) has screened hundreds of anthracycline analogs for antitumor activity. From these studies it can be concluded that (1) the amino sugar is not required for activity, (2) disaccharide analogs are generally more active than the parent saccharide in inhibiting RNA synthesis, and (3) in the aglycone, substituents in the 7 and 9 positions are important for activity. Studies have also shown

that if the 4′-hydroxyl group is removed, cardiac toxicity is lessened significantly [322–324]. Thus, it seems that the amino sugar and/or the 4′-hydroxyl group are major determinants of cardiac toxicity in the anthracyclines.

5. Intercalating Anthracenes and Analogs

5.1. Mitoxantrone

Mitoxantrone hydrochloride (NSC-301739, DAD, CL-232315) [*070476-82-3*], 1,4-dihydroxy-5,8-bis[(2-(2-hydroxyethyl)amino)ethyl]amino-9,10-anthracenedione, is a new type of antineoplastic agent. Mitoxantrone is active against breast cancer, acute leukemia, lymphoma, cervix carcinoma, and liver cell cancer. Unlike the anthracyclines that have a red color, the anthracenediones are deep blue. Mitoxantrone is structurally similar to adriamycin but without the aminosugar at C9 and can be synthesized starting from 1,8-dihydroxyanthrachinone [325–329].

Trade names: Novanthrone (Lederle / American Cyanamide); Onkotrone (ASTA Medica AWD).

Mitoxantrone

Mechanism of Action. The quinone structure of mitoxantrone was recognized as being similar to that of adriamycin, having a lower cardiotoxic potential. However, its discovery was both a result of serendipity and of rational drug development [325]. The exact mechanism of action by which mitoxantrone exerts its cytotoxic effects has not been fully defined. The cytotoxicity is most likely associated with the action on chromosomal elements, resulting in DNA damage and leading to inhibition of nucleic acid synthesis and the eventual death of the cell. When compared to doxorubicin on an equimolar basis mitoxantrone proved to be six to seven times more potent in inhibiting the incorporation of uridine and thymidine into DNA [330]. Mitoxantrone is a cell phase nonspecific agent and has wide spectrum of activity against several experimental animal tumors. Cross-resistance to adriamycin was not always seen [331–333]. Adriamycin-like cardiac toxicity was not found in comparative studies using rats, dogs, rabbits, and monkeys maybe partially due to inhibition of free radical formation and due to the lack of the amino sugar moiety [334], [335]. Although mitoxantrone is not entirely free of cardiac toxicity in humans, minimal nausea and vomiting was observed [336–341].

5.2. Analogs

Bisantrene hydrochloride (NSC-337766, ADD, CL-216942) [*071439-68-4*], 9,10-anthracenedicarboxaldehyde bis[(4,5-dihydro-1H-imidazol-2-yl] dihydrochloride, $C_{22}H_{22}N_8$’2 HCl, M_r 471.39, is an intercalating anthracenebishydrazine cytostatic [342–344]. The product was launched for treatment of acute non-lymphocytic leukemia [345].

Trade names: Zantrene and Cyabin (Lederle).

As solubility is a problem, bisantrene prodrugs with enhanced water solubility (e.g., 199344, see below) were developed [346–348].

Bisantrene

199344

Further intercalating agents such as amsacrine (NSC-156303/NSC-249992, m-AMSA, SN-11841) [*051264-14-3*] [349], [350], or nitracin [*4533-39-5*] [351] have the acridine structure in common.

Trade names: Amsacrine is marketed as Amsidine, Amecrin, and Ansidyl (Parke-Davis) [352–354].

Amsacrine

6. Antitumor Antibiotics Other than Anthracyclines

The antitumor antibiotics are a group of microbial products capable of inhibiting tumor growth. This class of antitumor agents has been extensively studied as to mechanism of action and has a rather broad spectrum of activity. In contrast to antibacterial antibiotics, the therapeutic index of these drugs tends to be narrow and toxicity to normal host tissues is considerable.

6.1. Actinomycin D (→ Antibiotics, Chap. 3.7.6.)

The actinomycins are a family of antibiotics derived from *Actinomyces* broths during the 1940s [357]. Structurally, compounds in this class share a common phenoxone ring and two cyclic pentapeptides. The natural products differ among themselves in the amino acid composition of the peptide chains, but only actinomycin D is used in the clinical treatment of cancer, where it demonstrates reproducible activity against gestational choriocarcinoma and Wilms' tumor.

Actinomycin D (NSC-3053) [*50-76-0*], dactinomycin, $C_{62}H_{86}N_{12}O_{16}$, M_r 1255.47.

Mechanism of Action. Actinomycin interacts with DNA through "pseudo-intercalation" at deoxyguanylyl-3′,5′-deoxycytidine sequences [358], [359], resulting in inhibition of DNA-directed RNA synthesis and inhibition of protein synthesis [360]. Resistance to actinomycin D is linked to cross-resistance against other structurally unrelated amphiphilic drugs with dissimilar mechanisms of action as part of the phenomenon of pleiotropic drug resistance (see Section 4.2). Certainly it had been previously demonstrated that the accumulation of drug is greater in sensitive cells [361], [362], suggesting that alterations in transport at the membrane level might be important to resistance.

6.2. Bleomycin (→ Antibiotics, Chap. 3.7.1.)

Bleomycins (NSC-125066) are a group of antitumor antibiotics initially isolated from broths of *Streptomyces verticillus* [363].

Actinomycin D

The fermentation product consists of approximately 12 different components clinically marketed as bleomycin. Each is a peptide with a low relative molecular mass (ca. 1500), all containing bleomycinic acid but differing in terminal alkylamine groups. The clinical product is approximately 60–70 % bleomycin A_2 (NSC-146842), N^1-[3-(dimethylsulfonio)propyl]bleomycinamide, $C_{55}H_{84}N_{17}O_{21}S_3$, M_r 1416; and 20–30 % bleomycin B_2. Other analogs comprise about 5 % of the total. The drug is highly active against germ cell neoplasm of the testis.

6.2.1. Analogs

Peplomycin [*68247-85-8*], N^1-{3-[(1-phenylethyl)amino]propyl}bleomycinamide, $C_{61}H_{88}N_{18}O_{21}S_2$, M_r 1473.62, a biosynthetic bleomycin analog, demonstrates significantly reduced pulmonary toxicity in rodents [364]. The toxicology studies are supported by clinical trials in Japan (initiated in 1981) and France (1983), and suggest that peplomycin has a greater therapeutic index than the parent compound and may replace bleomycin in the clinic [365]. In addition, total synthesis of bleomycin described in the 1980s will likely lead to other analogs and a further understanding of the drug's mechanism of action [367]. A new drug delivery system which comprises peplomycin absorbed on to small activated carbon particles was introduced as slow release formulation suggesting to decrease the systemic toxicity [366].

6.2.2. Mechanism of Action

Bleomycin enters cells slowly. Labeling studies demonstrate that the drug is first detected on the cell membrane and reaches the nucleus only after several hours [368]. Bleomycin kills cells by producing single- and double-strand DNA breaks. Bleomycin first binds guanine bases in DNA through the amino terminal peptide of the drug [369]. Free-radical formation occurs through oxidation of a bleomycin–Fe(II) complex to Fe(III), which catalyzes the reduction of molecular oxygen to superoxides and free hydroxyl radicals [370]. In vitro resistance to the drug appears to be mediated either by defective accumulation [371] or by increased intracellular drug degradation by a specific bleomycin hydrolase [372–374].

The clinical toxicity of bleomycin is unusual. The drug has little hematopoietic toxicity; its major dose-limiting toxicities are to the lungs and skin. Acute and chronic pneumonitis followed by progressive pulmonary fibrosis appears to be dose dependent, with risk increasing significantly in patients receiving a cumulative dose of more than 450 mg. This toxic endpoint may be due to the terminal amines of the parent compound. This hypothesis is supported by preclinical studies [375] as well as by early clinical studies of peplomycin. The maximum-tolerated cumulative dose of this terminal amino acid-substituted bleomycin analog has yet to be determined, although during phase I analysis, pulmonary toxicity was not observed until weekly doses exceeded 10 mg/m^2 [376].

6.3. DNA Interactive Natural Products

Analogs related to the natural product CC-1065 like adozelesin, bizelesin, and carzelesin bind in the minor grove of the DNA and form a covalent adduct with adenine [377]. Adozelesin

CC-1065

Adozelesin

Bizelesin

Carzelesin

Duocarmycin C1

Pyrindamycin A

[*110314-48-2*] [378] is the clinically farthest advanced agent, while the prodrug carzelesin [*119813-10-4*] [379] and the dimer bizelesin [*129655-21-6*] [380] demonstrated impressive preclinical activity.

Further modified cyclopropylpyrroloindoles (CPI) forming covalent adducts with DNA are duocarmycin A [*118292-35-6*] [381], [382], pyrindamycin [*118292-36-7*] and FCE 24517 [383], [384].

A series of new DNA cleaving molecules based on the reactive enediyne moiety are the anticancer antibiotics calicheamicin [*113440-58-7*] [385], esperamicin [*114797-28-3*] [386], and dynemicin.

Simplified enediyne-type compounds damage DNA upon activation by chemical or biological means and are extremely potent cytotoxic agents in vitro [387], [388].

Esparamicin A1

Dynemicin A

7. Antitubulin Agents

Tubulin-containing structures are important for diverse cellular functions, including chromosome segregation during cell division, intracellular transport, development and maintenance of cell shape, cell motility, and possibly distribution of molecules on cell membranes. The drugs that interact with tubulin are heterogeneous in structure. A common characteristic of these agents is binding to tubulin, causing its precipitation and sequestration to interrupt many important biologic functions that depend on the microtubular class of subcellular organelles. The tubulin – drug aggregates can be visualized by the indirect immunofluorescence technique as brightly stained cytoplasmic paracrystals. Of the tubulin binders, those that are important in cancer medicine include vinca alkaloids, podophyllotoxins, and taxoids.

7.1. Vinca Alkaloids (→ Alkaloids, Chap. 11.3.4.)

Vinca alkaloids are dimeric indole derivatives isolated from the periwinkle plant, *Catharantus roseus.* Of the whole family of more than 70 naturally occurring alkaloids, only a few have cytotoxic activity.

7.1.1. Vincristine and Vinblastine

The molecular structures of the dimeric *Catharantus roseus* alkaloids vincristine (NSC-67574) [*57-22-7*], 22-oxovincaleukoblastine, $C_{46}H_{56}N_4O_{10}$, M_r 824.94, Oncovin (sulfate); and vinblastine (NSC-49842) [*865-21-4*], vincaleukoblastine, $C_{46}H_{58}N_4O_9$, M_r 811.00, Velban (sulfate hydrate), are very similar. Both are formed of multiringed units, vindoline and catharantine, linked by a carbon – carbon bridge. They differ only in the nature of the substituent on the vindoline nitrogen atom.

R^1 = CHO, R^2 = CO(OCH$_3$), R^3 = CO(CH$_3$), Vinristine
R^1 = CH$_3$, R^2 = CO(OCH$_3$), R^3 = CO(CH$_3$), Vinblastine
R^1 = CH$_3$, R^2 = CO(NH$_2$), R^3 = OH, Vindesine

Cellular Pharmacology. As yet it is not clear how vinca alkaloids cross cell membranes. Some data suggest an energy-dependent transport system [389], while other data suggest simple diffusion across membranes [390]. However, passive diffusion is important only at drug concentrations exceeding 100 μM. Transport of vincristine is completely inhibited by vinblastine, suggesting a common carrier.

Vincristine and vinblastine exert their biologic effect through binding to tubulin. This occurs in interphase (late S and G_2), producing a transient G_2 block [391]. They do not affect DNA synthesis directly. The metabolic consequences of tubulin binding include polyploidy, nuclear fragmentation, and inhibition of cytokinesis, which occurs after prolonged drug exposure. Present studies suggest that sensitivity to these drugs increases progressively as cells approach mitosis and that cells at the end of the cycle at the time of exposure are likely to exhibit the greatest degree of mitotic disorganization [391].

Vincristine and vinblastine share a common binding site on each tubulin monomer, with the binding affinity (K_d) of about 1.6×10^{-6} M. The drug concentrations necessary to produce 50 % cell kill in vitro are ca. 4×10^{-8} M [392]. Malignant lymphocytes appear more susceptible than normal lymphocytes, presumably because of high tubulin content expressed on the surfaces of leukemic cells [393]. Other metabolic effects include inhibition of DNA and RNA and protein synthesis. However, these effects are exerted only at very high drug concentrations (1000 times greater than those achieved in vivo) and probably are secondary phenomena.

Drug Interactions. Both vincristine and vinblastine potentiate the effect of methotrexate through their blockade of methotrexate exit from cells [394], [395]. Some amino acids (glutamine, aspartic acid, ornithine, citrulline, and arginine) completely reverse the cytotoxic effect of vinblastine in tissue culture [396].

Mechanisms of Resistance. Vinca resistance may arise through mutations in tubulin, leading to decreased drug binding. Vinca-resistant cells may also share cross-resistance with antitumor antibiotics through a separate mechanism of resistance. The precise mechanism of this pleiotropic drug resistance remains to be clarified. However, tubulin is not responsible for that phenomenon because there is very little difference in affinity binding of colchicine to tubulin isolated from drug-sensitive and drug-resistant cells [397]. The appearance of a novel glycoprotein on the membrane of resistant cells and the accelerated drug efflux – leading to impaired drug accumulation – seem, at present, to be the possible mechanisms responsible for resistance [398].

7.1.2. Vindesine

Vindesine (NSC-245467) [*53643-48-4*], 3-(aminocarbonyl)-O^4-deacetyl-3-de(methoxycarbonyl)vincaleukoblastine, deacetylvinblastineamide, $C_{43}H_{55}N_5O_7$, M_r 753.95 (structure, Section 7.1.1), is a vinblastine metabolite. It possesses antitumor activity that is similar to vincristine's rather than that of its parent compound, vinblastine. Vindesine demonstrates better activity than vinblastine in some tumor models (Gardner lymphosarcoma, Ridgway osteogenic sarcoma, and mammary carcinoma). In the past several years vindesine has attracted considerable attention among clinical investigators and has been intensively investigated. Response rates vary, with the highest responses observed in the highest lymphatic malignancies [399]. The drug is less neurotoxic than vincristine and appears to be active in vincristine-resistant tumors [400], [401].

7.1.3. Vinorelbine

Vinorelbine (KW-2307, NVB) [*071486-22-1*] 3',4'-didehydro-4'-deoxy-C'-norvincaleukoblastine, $C_{45}H_{54}N_4O_8$, M_r 778.94, is a semisynthetic vinca alkaloid. Starting from anhydrovinblastine the compound is obtained as 5'-noranhydrovinblastine in three steps [402], [403]. The product was launched for the treatment of non-small cell lung cancer.

Trade names: Navelbine (Pierre-Fabre/Glaxo), Ennades (Farmitalia).

Mechanism of Action. Vinorelbine was selected for drug development due to its high affinity for tubulin and its ability to prevent tubulin

polymerization [403–405]. The compound induced total depolymerization of microtubules in P 388 murine leukemia cells, possibly via stimulation of microtubular protein synthesis [403]. Vinorelbine and vincristine were equally active against L 1210 leukemia in mice, while vinblastine had no significant effect. Vinorelbine exerted significant antitumor activity in the vincristine-resistant cell line P 377/VCR and low cross-resistance to other vinca alkaloids was observed [406], [407].

In clinical studies leukopenia was dose-limiting, no thrombocytopenia was observed [408]. Efficacy in non-small cell lung cancer was demonstrated [409–411].

Vinorelbine

7.2. Podophyllotoxin and Its Derivatives

Podophyllin is a complex mixture of crystalline compounds derived from the mayapple plant. The active agent derived from this plant product, podophyllotoxin [*518-28-5*], shares a common binding to tubulin with colchicine, and the morphological effects of podophyllotoxin and colchicine exposure are indistinguishable [412]. The semisynthetic glycoside derivatives of podophyllotoxin, VP-16-213 (NSC-141540) [*33419-42-0*], etoposide, and VM-26 (NSC-122819) [*29767-20-2*], teniposide, have reproducible clinical activity against testicular cancer, small-cell lung cancer, and lymphomas [413].

R = CH_3

Teniposide (VM-26)

Despite structural similarities between the semisynthetic derivatives and parent natural product, neither VP-16 nor VM-26 binds tubulin. Evidence from a number of laboratories suggests that VP-16 exerts cytotoxic effects by causing DNA breakage [414], [415]. Selective double-strand DNA breaks, which are particularly lethal, appear to be caused by these agents [416].

The precise mechanism for VP-16 and VM-26 DNA damage is unknown, but the fact that the presence of a 4′-hydroxyl group is critical for cytotoxicity suggests formation of free-radical intermediates. Indeed, free-radical scavengers appear to be able to protect from podophyllin derivative cytotoxic effects in vitro [417]. Formation of DNA breaks may also be due to specific inhibition of the DNA repair enzyme topoisomerase II by both VP-16 and VM-26 [418]. It is likely that further characterization of topoisomerase II and the effects of its inhibition will result in the development of new leads in antitumor drug development.

7.3. Camptothecin and Analogs

Camptothecin (→ Alkaloids, Chap. 11.3.5.) (CPT) [*7689-03-4*], an alkaloid isolated from the Chinese plant *Camptotheca accuminata* in 1966 [419] was proved to have antineoplastic activity in various tumor systems [420]. The clinical use of CPT was, however, limited because of its high toxicity and low solubility in water. New derivatives have been synthesized carrying substitutents in 7,9,10- or 11-position of the ring A.

Campothecin

Irinotecan (NSC-616348, CPT-11, DQ-2805) [*097682-44-5*] [421], (+)-7-ethyl-10-[4-(1-piperidyl)-1-piperidyl]carbonyloxycamptothecin, $C_{33}H_{38}N_4O_6$, M_r 586.69 and topotecan (NSC-609699, SKF-S-104864-A, E-89/001) [*119413-54-4*] [422], (S)-10-dimethylaminomethyl-9-hydroxycamptothecin, $C_{23}H_{23}N_3O_5$, M_r 457.91 are camptothecin derivatives with topoisomerase I-inhibitory activity. As antineoplastic alkaloids, they can be synthesized semisynthetically starting from CPT [423]. In addition both agents have intercalating properties and are water soluble. Irinotecan hydrochloride was launched for the treatment of small cell and non-small cell lung cancer and cancers of the uterine, cervix, and ovaries.

Trade names: Campto (Rhône-Poulenc Rorer/Yakult Honsha) Topotecin (Daiichi Seiyaku).

Unlike irinotecan, topotecan is not a prodrug and does not require metabolic activation.

Irinotecan

Topotecan

Mechanism of Action. Topoisomerase (topo I) is an ubiquitous nuclear enzyme involved in the regulation of essential cellular functions by relieving torsional DNA strain. Relaxation of supercoiled DNA is achieved through a series of topo I-mediated reactions. The main physiological role of topo-I is in sensing and subsequently releasing the positive supercoiling generated ahead of the moving transcription apparatus. A number of malignancies including acute leukemia, blasts, colon, esophageal, and ovarian cancers contain increased topo-I levels as compared to normal tissues [424], [425]. Topotecan binding to topo-I-DNA adducts results in markedly decreased rates of nick resealing and in delayed enzyme release, leading to increased numbers of strand breaks [426].

In animal tumor models including xenografts of human cancer lines topotecan and irinotecan exhibit a wide spectrum of antineoplastic activity [427–429]. Cell lines overexpressing P-glycoprotein display low levels of resistance to topotecan through decreased drug retention, more pronounced resistance is found in cell lines containing low levels of topo I [430], [431].

Dose-limiting toxicity in patients were stomatitis and esophagitis as well as neutropenia [432].

7.4. Taxoids

Paclitaxel (NSC-125973, BMS-181339) [*33069-62-4*], $C_{47}H_{51}NO_{14}$, M_r 853.9, is a natural antineoplastic taxane derivative originally isolated from the plant *Taxus brevifolia* [433] and subsequently synthesized due to limited supply from the bark of endangered yew trees. Starting from 10-deacetyl baccatin III (isolated from the renewable twigs and needles of *Taxus baccata*) the compound can be prepared in three steps utilizing protected *N*-benzoyl-(2R,3S)-3-phenylisoserine as key building block [434–436]. Various synthetic approaches are described and patented, including three total synthesis of paclitaxel [437–440].

Paclitaxel has a novel mechanism of action. Unlike vincristine or vinblastine, which bind tubulin to inhibit tubulin polymerization, paclitaxel stabilizes microtubular structures [441]. Indicated for the treatment of primary ovarian cancer in combination with cisplatin and for

metastatic ovarian cancer where standard therapy has failed, paclitaxel has been marketed since 1993 as Taxol (Bristol-Myers Squibb) and was the best-selling anticancer agent in 1996. Taxol does not share a common binding site with other antitubulin agents and may instead bind to and stabilize polymerized tubulin [442].

A semisynthetic analog of paclitaxel, docetaxel (NSC-628503, RP-56976) [*114977-28-5*], (2R,3S)-*N*-carboxy-3-phenylisoserine, *N-tert*-butyl ester, 13-ester with 5β, 20-epoxy-1,2α-4,7β,10β,13α-hexahydroxytax-11-en-9-one 4-acetate 2-benzoate, $C_{43}H_{53}NO_{14}$, M_r 807.9, is a derivative with an *N-tert*-butyloxycarbonyl-(2R,3S)phenylisoserine C-13 side chain. Docetaxel is more potent than paclitaxel in vitro [443], [444]. Impressive clinical results have been reported for the treatment of ovarian, breast, and bronchial cancers with docetaxel [445]. The compound was launched in 1996 for the treatment of locally advanced breast cancer or relapse during anthracycline therapy of NSCLC and breast cancer.

Trade name: Taxotere (Rhône-Poulenc Rorer).

Paclitaxel

Docetaxel

Mechanism of Action. More than two decades after its isolation and the elucidation of its complex structure and cytotoxic activity [433] interest in paclitaxel raised again when S. Horwitz et al. [446] reported on the novel mechanism of action. As spindle poison paclitaxel promotes the polymerization of tubulin to microtubules and stabilizes them against depolymerization, whereas vinca alkaloids induce microtubule disassembly (see Fig. 2). Thus, with paclitaxel the dynamic equilibrium of assembly and disassembly of microtubules is shifted in favor of the polymer, preventing cell division [447]. Paclitaxel binds preferentially to the β-tubulin subunit. This binding is reversible and the site is different from the binding sites of vinca alkaloids, colchicine and podophyllotoxin [448–450]. If paclitaxel is present, tubulin polymerizes without exogenous GTP and these stabilized, rigid microtubules cannot be disassembled. As a result, the dynamic organization of the cell is interrupted which leads to irreversible damage in rapidly dividing cells. Further evidence has been reported that the antiproliferative activity of paclitaxel is caused by additional effects [451–453].

A major impediment in the development of taxol as a drug was its poor water solubility [454]. With the solubility enhancer Cremophor EL hypersensitivity reactions, including hypotension, urticaria, and dyspnea, occurred in patients during rapid infusion. To cope these allergic reactions, 24-hour infusions and pretreatment with dexamethasone, diphenhydramine, or cimetidine was recommended [455].

The dose-limiting *toxicity* of paclitaxel is neutropenia. Several other toxic effects such as diarrhea, nausea, and emesis are less common. Docetaxel shares many toxic effects with paclitaxel such as dose-limiting neutropenia, alopenia, myalgias, and mucositis. In addition fluid retention and cutanous toxicities are observed [445], [460], [461]. Because of the low water solubility of paclitaxel and docetaxel, the synthesis of more soluble taxoid prodrugs and smaller analogs has become an interesting area of research (see Section 7.5).

Structure – Activity Relationship. A large number of taxoid analogs has been synthesized with emphasis to enhance biological activity and to improve the water solubility [436]. C-13

Figure 2. Mechanism of action of paclitaxel and vinca alkaloids

side chain depleted analogs such as baccatin III and its derivatives [456] as well as *N*-benzoyl-(2R,3S)-phenylisoserine are inactive. Simplified side chains at C-13 (like acetic, crotonic, or phenylacetic acid) possess reduced activity.

3'-Cyclohexyl-3'-dephenylpaclitaxel has a similar cytotoxicity to paclitaxel. Further modifications in the aromatic 3'-phenyl group gave compounds that were equipotent with paclitaxel. The compound with a 3'-(*p*-methoxyphenyl) has a slightly increased activity. Compounds with different substituents in the *N*-benzoyl part were similar to paclitaxel if these substituents were aromatic, aliphatic substituents reduced cytotoxicity.

As the 2'-hydroxyl group is essential for maximal biological activity [457] esterification leads to a total loss of activity in the microtubule assay, whereas cytotoxicity remains unchanged. Thus various amino acid esters were produced as prodrugs.

Notable loss of cytotoxicity was observed with A-ring modified analogs and oxidation at C-10 or C-7. 7-Acetylpaclitaxel and the C-7 epimer were similar in their ability to inhibit cell proliferation. All derivatives without the intact oxetane moiety are inactive [458]. Further, all C-4 modified analogs were devoid of activity underscoring the vital importance of these functional groups [459].

7.5. Epothilone A and B

The high cytotoxicity and good stabilization of microtubule raised interest in the natural products epothilone A [*152044-53-6*] and B [*152044-54-7*] originally isolated from myxobacteria *Sorangium cellulosum* [462]. Since Bollag et al. [463] reported on the mechanism of action, which resembles that of paclitaxel numerous reports were published on total synthesis [464–468] and biology of epothilones. Their unique capability to inhibit taxol resistant tumor cell lines [470] and their good solubility in water are the biggest advantages as compared to paclitaxel. Their in vivo activity is similar to that of paclitaxel [469].

R = H, Epothilone A
R = CH_3, Epothilone B

8. Heavy-Metal Complexes

8.1. *cis*-Platinum

cis-Platinum (NSC-119875) [*15663-27-1*], *cis*-diamminedichloroplatinum, cisplatin, $PtCl_2(NH_3)_2$, M_r 300.05, was the first heavy-metal compound to be introduced into clinical cancer chemotherapy. The discovery of this unique agent was predicated on the serendipitous observation that bacterial growth was inhibited when culture medium was subjected to an alternating current using platinum electrodes [471]. Moreover, the spent medium itself developed bacteriocidal characteristics, even in the absence of electrical current. Detailed analysis confirmed that, of the several platinum species produced by electrolysis, it was the cis isomer of $PtCl_2(NH_3)_2$ that had antibacterial activity. In 1969, Rosenberg and co-workers reported that *cis*-platinum also had potent antitumor activity in murine tumors [472], and phase I clinical studies with the drug were initiated two years later [473], [474]. *Cis*-platinum, in combination with other agents, has led to highly active and often curative regimens in patients with testic-

ular, ovarian, and head and neck cancer [475], [476].

8.1.1. Mechanism of Action

As with the alkylating agents, one of the major factors mediating the cytotoxicity of *cis*-platinum is probably the formation of cross-links between opposing strands of DNA (interstrand cross-links), linkage within a single strand of DNA (intrastrand cross-links), or the formation of linkages dependent on the hydrolysis of *cis*-platinum in solution. While the covalent stability of $Pt-NH_3$ bonds is high, both chlorides are good leaving groups and can be displaced by water or hydroxyl ions to form positively charged, aquated platinum species that avidly react with nucleophilic sites on macromolecules, especially the N^7 position of guanine and the N^3 position of cytosine [477]. Formation of the active intermediate is inhibited in the presence of Cl^-; in plasma the Cl^- concentration is sufficient to inhibit aquation of the drug, which has an in vitro plasma half-life of several hours [478]. However, this process occurs rapidly in the intracellular milieu, where Cl^- concentrations are low.

The cis configuration is central to cytotoxicity; the trans isomer is devoid of antitumor effects. This fact suggests that of the reactions caused by the aquated platinum species, formation of intrastrand cross-links is most important (intrastrand cross-links cannot be formed by the inactive trans compound).

As a result of nucleophilic attack on macromolecules, *cis*-platinum causes changes in the structural conformation of DNA [479] as well as intra- and interstrand cross-links. These changes inhibit RNA transcription from the DNA template [480] and, probably more important, directly inhibit DNA synthesis itself [481]. In addition, *cis*-platinum can react with tumor cell membrane to cause presentation of new antigenic determinants [482]. Whether this mechanism is related to tumor cell recognition and immune response remains to be determined.

As a heavy-metal-based compound, *cis*-platinum has unique clinical toxicities, including renal tubular damage, severe nausea and vomiting, high-tone hearing loss, and peripheral neuropathy. Less common are myelosuppression, hemolytic anemia, hypomagnesemic tetany, allergic reactions, and hepatotoxicity. Nephrotoxicity was dose limiting in early clinical trials and appeared to be due to tubular reabsorption of active platinum species causing proximal and distal tubule necrosis [483–485]. Tubular damage has been reported to cause defective reabsorption of magnesium, resulting in hypomagnesemia (which may result in tetany) [486], [487], as well as inappropriate renal loss of calcium, potassium, and phosphorus [488]. The acute renal toxicities of *cis*-platinum appear to be secondary to activation of the renin – angiotensin system, resulting in reduced renal blood flow and glomerular filtration [484], [489]. Thus, this toxicity can be mitigated by high-volume diuresis [490]. In 1984 it has been demonstrated that even high doses of *cis*-platinum are well tolerated when administered with high-volume chloresis, which not only dilutes urinary platinum levels but also prevents leaving of the chloride groups to form the toxic aquated molecule [491]. When administered by this regimen, the limiting side effects of *cis*-platinum become neurotoxicity and myelosuppression, while renal function is remarkably spared.

8.1.2. Mechanisms of Resistance

Although bacterial resistance to *cis*-platinum appears to be due to increased efficiency of DNA repair [492], the mechanisms of tumor cell resistance are less clear. Alkaline elution studies have demonstrated a direct relation between DNA cross-linking and tumor cell resistance [493–495], and a *cis*-platinum-resistant murine leukemia line has been described in which cross-links are formed at a reduced rate [496]. However, it remains uncertain whether this resistance is secondary to accumulation, impaired activation, or altered DNA repair processes. As with the alkylating agents in general, high levels of metallothionein have been reported in *cis*-platinum-resistant cells [497]. This sulfhydryl-rich protein is known to protect from metal toxicity by specifically binding to platinum, cadmium, and other heavy metals [498].

Because the cellular mechanisms of resistance to *cis*-platinum are so poorly characterized, new platinum analogs in clinical trial have

been selected in an attempt to reduce host toxicity with the aim of improving therapeutic index [499].

8.2. Carboplatin

Carboplatin (NSC-241240, CBDCA) [*839805-03-3*], *cis*-diammine[1,1-cyclobutanedicarboxylato-(2)-*O,O'*]platinum(II), $C_6H_{12}N_2O_4Pt$, M_r 371.3, is a second generation cisplatin analog without significant nephrotoxicity or neurotoxicity and with less emetic potential than the parent compound [500–503]. Clinical trials show activity against several tumor types. Carboplatin is especially effective in treatment of ovarian and small-cell lung cancer [504], [505]. The minimal emetogenic dose of *cis*-platinum in dogs is 9 mg/m^2, whereas for carboplatin the dose is 624 mg/m^2. In addition, this compound retains antitumor activity in *cis*-platinum-restistant murine leukemia [506], demonstrating consistent antitumor activity in patients with ovarian cancer in the absence of either ototoxicity, nephrotoxicity, or neuropathy [507], [508]. Carboplatin entered the market in 1989 and is the leading platinum complex cancer drug with sales of $ 373 × 10^6 worldwide in 1996. Carboplatin is indicated for the treatment of ovarian cancer and sales have benefited from the drug's use in combination with Taxol [509–512].

Trade names: Paraplatin (Bristol-Myers Squibb), Carboplat (BMS).

Carboplatin

8.3. Analogs

The synthesis and development of "second-generation" platinum compounds such as carboplatin has modified the problem of nephrotoxicity. Iproplatin (NSC-256927, CHIP) [*34348-60-2*], dichlorodihydroxy-bis-(2-propanamine)platinum $C_6H_{20}Cl_2N_2Pt$, M_r 418 [514], nedaplatin (NSC-375101D, 254-S), [*095734-82-0*], *cis*-diamine(glycolato-O^1,O^2)platinum, $C_2H_8N_2O_3Pt$, M_r 303.19 [515], and oxaliplatin (OHP) [*61825-94-3*], [Sp-4-2-(1R-*trans*)](1,2-cyclohexanediamine-*N,N'*)[ethanedioxato(2$^-$)-*O,O'*]-platinum, $C_8H_{14}N_2O_4Pt$ [516] were clinically investigated in depth. Nedaplatin entered the market in 1997 for the treatment of head and neck, small-cell lung, non-small cell lung, esophageal, bladder, testicular, ovarian, and uterine cervical cancers [517–520].

Trade name: Agupla (Shionogi).

Further studies of additional "third-generation" compounds are centering on the elimination of toxicity, enhanced therapeutic activity, non-cross-resistance and selective drug delivery [521]. Ormaplatin (NSC-363812, U-77233) [*62816-98-2*] [±(*trans*)]-tetrachloro(1,2-cyclohexanediamine-*N,N'*]platinum, $C_6H_{14}Cl_4N_2Pt$ and Lobaplatin (D-19466) [*135558-11-1*] are representatives of a series of platinum complexes in clinical development [522–524].

Nedaplatin

Lobaplatin

Iproplatin

Oxaliplatin

Ormaplatin

Orally active cisplatin-analogs with higher therapeutic ratio and specifically high anticancer activity are the challenge in the search for new "fourth-generation" derivatives. Platinum(IV)-complexes like JM 216, drug targeting approaches, e.g., the use of ligands with hormone receptor-binding affinity [525] or intercalating structures [526], and special formulation techniques are the major focus.

9. Hormonally Active Anticancer Drugs/Antihormones

Hormones and in particular, the sex hormones were the first growth factors discovered to be involuntary helpers of cancer. Female breast cancer and male prostate cancer are the best known examples of tumors acknowledged to be hormone-dependent. Shutting down the main production site of the sex hormones estrogen and testosterone either by removing the ovaries or by castration is a well-known and often effective therapy; however, these procedures can be problematic due to the concomitant psychological stress. Modern hormone therapy for advanced breast cancer and prostate cancer attempts to spare the patient such irreversible operative procedures for as long as possible by using hormone antagonists. Examples are the antiestrogens or LHRH antagonists, which hinder deployment of the hormone itself and thus its growth-promoting activity.

9.1. Antiestrogens (→ Hormones, Chap. 3.5.4.)

9.1.1. Antagonists

Estrogens can induce hormone-dependent human breast carcinoma and stimulate tumor growth. Reduced estrogen production is correlated with a lower risk of breast cancer and in particular with tumor regression. Hormonally active drugs are considered to be the treatment of first choice for advanced breast cancer, unless metastatic complications require immediate aggressive chemotherapy.

9.1.2. Tamoxifen, Toremifene

The antiestrogen tamoxifen (ICI 46474) [*10540-29-1*], (Z)-2-[*p*-(1,2-diphenyl-1-butenyl)phenoxy]-*N,N*-dimethylethylamine, $C_{26}H_{29}NO$, has become the standard first-line agent in postmenopausal patients [527–529]. The product is indicated for the treatment of breast cancer with worldwide sales of $\$561 \times 10^6$ in 1996.

Trade name: Nolvadex (Zeneca).

However, primary and secondary resistance to tamoxifen treatment requires the introduction of new analogs with improved therapeutic activity for hormon-dependent neoplasia. Toremifene (NK-622, Fc-1157a) [*089778-26-7*] [530], [531], 2-[*p*-[(Z)-4-chloro-1,2-diphenyl-1-butenyl]phenoxy]-*N,N*-dimethylethylamine, $C_{26}H_{28}ClNO$, M_r 405.97, raloxifene [532], and droloxifene [533] were investigated clinically.

Toremifene is a novel triphenylethylene derivative structurally related to tamoxifen [527–529]. Almost all compounds related to tamoxifen contain an alkylaminoethoxy side chain, which seems to be essential for their binding to the estrogen-receptor (ER) and antiestrogenic activity [536].

Trade names: Toremifene has been launched as Fareston (Farmos, ASTA Medica) and Estrimex (Adria) for treatment of postmenopausal breast cancer.

Tamoxifen

Toremifene

Mechanism of Action. Tamoxifen and toremifene bind to estrogen receptors in the cytosol, are translocated to the nucleus, and block estrogen-induced cell proliferation. However, specific differences in the drug profiles exist, indicating improved therapeutic properties of toremifene compared with tamoxifen. These differences include lower intrinsic estrogenic activity, longer nuclear retention, no retinal damage or neoplastic liver changes. Toremifene is more active against dimethylbenz[a]anthracene (DMBA)-induced rat mammary cancer

and unlike tamoxifen, it inhibited the growth of an ER-negative transplantable mouse uterus sarcoma, although the antitumor effect of this compound was preferentially directed against estrogen-dependent tumors of the mammary gland and endometrium [534], [535]. In clinical trials no concrete side effects or pathological clinical chemistry values were observed in most patients [537], [538]. Some patients complained of light hot waves, sweating, nausea, and transient vertigo.

Cytotoxicity in vitro, dose related activity in ER-positive (i.e., cancer cells containing estrogen receptors) and ER-negative tumor models suggest that additional mechanism like growth-factor production may be triggered by toremifene [539].

9.1.3. Analogs

Raloxifene (LY-139481) [*82640-04-8*] is a benzo(b)thien-3yl-antiestrogen formerly under development for treatment of breast cancer. It mimics the effects of estrogen on the skeleton and is therefore effective in the prevention of postmenopausal osteoporosis [540]. Faslodex (ICI-182780, ZD-182780) [*129453-61-8*] is a pure, steroidal estrogen antagonist with oral anticancer activity [541], [542]. The in vivo antitumor activity of faslodex in xenografts of MCF-7 and Br 10 human breast cancers in mice was equivalent to that of tamoxifen. Miproxifene phosphate (Tat-59) [*115767-74-3*] [543], panomifene (Gyki-13504) [*77599-17-8*], idoxifene [544] (SB-223030, CB-7432) [*116057-75-1*] and droloxifene [*83647-29-4*] are more potent than tamoxifen against estrogen-dependent tumors in mice.

9.2. Aromatase Inhibitors (→ Hormones, Chap. 3.5.4.)

All endocrine therapies inhibit endogenous estrogen production or the interaction between estrogens and cellular estrogen receptors. Both ablative and additive hormone therapies are equal in efficiency.

Aromatase inhibitors block cellular estrogen synthesis and thus induce, particularly during postmenopause, a marked decrease in estrogen production. The inhibition of estrogen synthesis is caused by a suppression of the enzyme aromatase which converts androstenedione to estrone [545].

Aminoglutethimide [*125-84-8*], (±)-2-(4-aminophenyl)-2-ethylglutarimide, an unspecific aromatase inhibitor which also suppresses adrenal desmolase and 11-β-hydrolase, was the first aromatase inhibitor in the clinic and on the market.

Trade name: Orimeten (Ciba-Geigy).

Aminoglutethimide induces a decrease in cortisol, followed by an increase in ACTH [546]. Therefore new powerful specific aromatase inhibitors without influence on adrenal steroid synthesis were developed.

Formestane (4-OHA; CGP-32349) [*000566-48-3*], 4-hydroxyandrost-4-ene-3,17-dione, $C_{19}H_{26}O_3$, M_r 302.41, is an androstane derivative with highly specific aromatase inhibition [547]. The substance is used for the treatment of advanced breast cancer in postmenopausal women [548–553].

Trade name: Lentaron (Ciba-Geigy).

Atamestane, exemestane, and NKS-01 are orally active steroids.

Formestane

Atamestane

Exemestane

NSK-01

In addition to steroidal also nonsteroidal, in particular, imidazole/triazole derivatives were investigated as aromatase inhibitors. Anastrazole (ICI-D1033, ZD-1033) [*120511-73-1*] [554], 2,2'-[5-(1H-1,2,4-triazol-1-ylmethyl)-1,3-phenylene]-bis(2-methylpropionitrile), $C_{17}H_{19}N_5$, M_r 293.37, fadrozole (CGS-16949A) [*102676-96-0*] [555], (±)-4-(5,6,7,8-tetrahydroimidazo[1,5-a]pyridin-5-yl)benzonitrile, $C_{14}H_{13}N_3$, M_r 259.74, letrozole (CGS-20267) [*112809-51-5*] [556], 4,4'-(1H-1,2,4-triazol-1-ylmethylene)bis[benzonitrile], $C_{17}H_{11}N_5$, and vorozole (R83842), [*129731-10-8*] [557], (+)-6-[(4-chlorophenyl)-1H-1,2,4-triazol-1-ylmethyl]-1-methyl-1H-benzotriazole, $C_{16}H_{13}ClN_6$, are highly selective nonsteroidal aromatase inhibitors without intrinsic androgenic or estrogenic properties.

Trade names: Anastrazole and Fadrazole are marketed as Arimedex (Zeneca) and Arensin (Ciba-Geigy), respectively, for treatment of postmenopausal breast cancer.

Another aminoglutethimide analog in development is rogletimide [558] (pyridoglutethimide) [*121840-95-7*], (±)-3-ethyl-3(4-pyridinyl)-2,6-piperidinedione, $C_{12}H_{14}N_2O_2$.

Fadrazole

Letrozole

Vorozole

Rogletimide

Anastrazole

YM-511

Aminoglutethimide

Mechanism of Action. Fadrazole [559] and anastrazole [560–567] for example, were found to be potent and specific aromatase inhibitors with neither androgenic nor estrogenic activity. Fadrazole was 180 times more potent than aminoglutethimide as an aromatase inhibitor. Anastrazole inhibited human placental aromatase with an $IC_{50} = 15$ nM (IC_{50} = inhibitory concentration). In animal studies fadrazole was found to lower serum estrogen, raise luteinizing hormone (LH) level, and reduce uterine weight as a result of aromatase inhibition. In addition, administration of 2 mg per kilogram body weight caused regression of DMBA-induced mammary tumors in female rats. In humans half-life of, e.g., anastrazole was more than 30 h. No serious side effects were reported and no significant effects on cortisol or aldosterone secretion was observed.

9.3. Antiandrogens

Prostate cancer is primarily a disease of the elderly and the second most common cancer in men in the United States. Ever since HUGGINS and HODGES demonstrated the partial androgen dependence of most prostatic tumors more than 50 years ago, androgen deprivation has become the commonly used initial treatment for prostate cancer [568], [569].

The major circulating androgen in man is testosterone, 90 % of which is produced in the testis. In addition, a small amount of androgen is produced by the adrenal gland under the control of ACTH. (see Fig. 3).

Four ways for androgen deprivation exist:

1) Removal of organs by surgery
2) Interference with control mechanism
3) Inhibition of biosynthesis
4) Competitive inhibition of androgens at the receptor site

The group 2 approach with, e.g., LHRH agonists and antagonists will be discussed in Section 9.4. Examples of group 3 include compounds (e.g., ketoconazole), which inhibit the synthesis of adrenal androgens [570] as well as inhibitors of the enzymes 5α-reductase [571] and aromatase [572]. "True" antihormones are compounds of group 4, based on the definition that an antiandrogen is a substance which binds to the target tissue androgen receptor and prevents the stimulatory effects of androgens. Although the exact mechanism of action of antiandrogens is not totally understood, an important feature is the competitive inhibition of the binding to the cytosol receptor. The first antiandrogen to be used clinically was the synthetic steroidal antiandrogen cyproterone acetate [*427-51-0*] [573]. However, cyproterone acetate also exhibits other steroidal activities, it is, e.g., a potent progestin, exhibits weak antigonadotrophic activity and has glucocorticoid like properties. Beyond the success in treating prostate cancer the steroidal properties are largely responsible for the fluid retention and thrombosis seen in patients [574]. Therefore, nonsteroidal antiandrogens are expected to have advantages by avoiding steroid-related side effects [575].

9.3.1. Flutamide

Flutamide (Sch-13521, NK-601, FTA) [*013311-84-7*], 2-methyl-*N*-[4-nitro-3(trifluormethyl)phenyl]-propanamide, $C_{11}H_{11}F_3N_2O_3$ was discovered in the early 1970s. Unlike the steroids it can easily be synthesized [576], [577]

and is devoid hormonal activities. Total sales of the product were $ 271 × 10^6 in 1996.

Trade names: Eulexin and Drogenil (Schering-Plough).

Mechanisms of Action. In a comparative study in castrated rats flutamide was shown to be equipotent to cyproterone acetate as an antiandrogen [578]. Several groups had observed that flutamide was a more potent antiandrogen in vivo than in vitro and suggested the involvement of an active metabolite [579], [580]. The major metabolite was identified as 2-hydroxyflutamide analog (Sch-16423) [*52806-53-8*] and high levels of 2-hydroxyflutamide in the plasma led to the conclusion that this was the active form of flutamide [581]. Although the plasma levels of testosterone increased on flutamide treatment, the levels of testosterone and dihydrotestosterone in androgen target tissue were reduced [582]. Flutamide exerts its antiandrogenic action by blocking the binding of androgens to the cytosolic androgen receptor and / or inhibiting the nuclear binding of androgens in the target tissue [581].

In patients improvements were seen in pain relief, prostatic enlargement and induration, reduction of metastases, and increase in body weight and phosphatase. Most common side effects of flutamide therapy are gynecomastia and breast tenderness [584]. More recent trials use a combination of flutamide with LHRH agonists (see Section 9.4). This is the concept of maximal androgen withdrawal in which the LHRH agonist wipes out androgens of testicular origin and the antiandrogen blocks the action of androgens of adrenal origin at the androgen receptor [585–587]. The therapeutic benefits seem to be greatest in patients with minimal disease at the start of treatment.

Flutamide

9.3.2. Nilutamide

Nilutamide has been discovered bei Roussel-Uclaf.

Trade name: Anandron (Roussel-Uclaf).

Mechanism of Action. Nilutamide competitively inhibits binding of androgens to the cytosolic androgen receptor. Administration over 7 days to immature, castrated male rats, nilutamide inhibited the increase of prostate weights induced by testosterone in a dose-dependent manner [588]. In rat pituitary cells nilutamide reverses the inhibition of LHRH-induced LH release elicited by dihydrotestosterone. It is probably because of these effects that nilutamide is recommended for use only in surgically or medically castrated males [589]. Nilutamide has demonstrated an antiandrogenic action in several animal tumor models [590].

Single dose kinetics of nilutamide in volunteers (100 mg) indicate a half-life of 43 ± 3 h, compared to 5.2 h for flutamide (200 mg) [591].

Clinical trials with nilutamide have concentrated on combination therapy with surgical or medical castration. The side effects observed in patients include hot flushes, nausea, vomiting, and visual problems [592].

Nilutamide

9.3.3. Bicalutamide

Bicalutamide (ICI-176334) [*090357-06-5*], (±)-4-[3-(4-fluorophenylsulfonyl)-2-hydroxy-2-methylpropionamido]-2-(trifluoromethyl)benzonitrile, $C_{18}H_{14}F_4N_2O_4S$, M_r 430.37 was discovered at ICI / Zeneca and selected from more than 1000 compounds as having the desired properties of a pure, nonsteroidal, peripherally selective antiandrogen [593], [594]. The product was launched for the treatment of advanced prostate cancer in combination with LHRH analogs or surgical castration.

Trade name: Casodex (Zeneca).

Mechanism of Action. Bicalutamide inhibits the binding of the synthetic androgen [^{3}H]-R-1881 to both rat prostate and pituitary cytosol androgen receptors. The substance

binds some 50 times less effectively than dihydrotestosterone and about 100 times less effectively than R-1881 to the prostate androgen receptor, Its affinity for the prostate receptor is about four-fold higher, that for the pituitary receptor ten times higher than that of hydroxyflutamide [595]. In vivo studies revealed that bicalutamide is about five times as potent as flutamide after oral application. Bicalutamide did not cause a significant elevation in LH or testosterone at any of the doses tested, whereas flutamide elicited increases. Half-life of bicalutamide in prostate cancer patients who received 10, 30 or 50 mg/d bicalutamide was around 6 d. The compound was well tolerated in all doses [596–598].

Nilutamide and bicalutamide offer advantages over flutamide because of their long half-lifes and sustained serum levels on once-daily dosing. The latter is essential to prevent androgen stimulation.

Bicalutamide

9.4. LHRH Analogs (→ Peptide and Protein Hormones, Chap. 2.1.)

The releasing hormone gonadorelin (GnRH, synonymous with LHRH, luteinizing hormone-releasing hormone or gonadoliberin), together with its specific receptor, plays a central role in neuroendocrinology [599]. The decapeptide LHRH is formed in the cell bodies of hypothalamic neurons and is secreted in pulses into the blood stream [600–603]. Ultimately it stimulates secretion of the sex-specific hormones in the testes and ovaries. Specific receptors for LHRH and synthetic analogs are also present in the pituitary gland and other tissues (for example, tumor cells) [604] and organs.

Three concepts for therapeutic application have emerged. The first is the restoration of normal physiology by administration of LHRH by infusion pump to promote fertility in men and women who are infertile due to defective endogenous LHRH secretion. Second, long-lasting LHRH agonists (so-called superagonists) are used in a depot form, which bring about desensitization of the pituitary receptors and thus interrupt the signal cascade. This results in a biochemical "castration", which opens up new therapeutic possibilities for hormone-dependent diseases such as prostate cancer, breast cancer, and endometriosis. Although superagonists are generally well tolerated, they have the disadvantage that hormone secretion (estrogen, testosterone) is initially stimulated before the depletion of receptors or "down" regulation can take place, and thus the illness temporarily worsens [605]. This has led to the development of the third concept: use of LHRH antagonists [606] (see Fig. 3). In the late 1980s about 5000 LHRH analogs had been synthesized worldwide and tested in vitro or in vivo [607–609]. Whilst LHRH agonists have been on the market for about ten years, the LHRH antagonists that have been developed farthest are still in clinical testing [610–614].

9.4.1. LHRH Agonists

The first years after the discovery of the gonadorelins were marked by the search for more active agonists, since the therapeutic potential of gonadorelins as, for example, antitumor agents or in gynecology, was apparent [606], [615]. Such superagonists bring about a very effective reversible inhibition of the release of steroidal sex hormones. The exchange of glycine at postion 6 ($glycine_6$) of the native LHRH for other, always D-configured, amino acids, is common to all modern superagonists; some have a *C*-terminal ethylamide (buserelin, leuprorelin) or azaglycinamide (goserelin) residue instead of glycinamide. Eight to ten amino acids of the LHRH sequence are thus conserved in all clinically relevant superagonists; by exchange at a maximum of two positions, the biological activity or hormone suppression in tumor patients, can be increased by a factor of up to 100 on subcutaneous application [606], [615]. Table 1 summarizes the most important derivatives.

Buserelin (Profact, Suprecur) [*57982-77-1*], leuprorelin (Lupron, Carcinil, Enatone) [*53714-56-0*], triptorelin (Decapeptyl) [*57773-63-4*], and goserelin (Zoladex) [*65807-02-5*] (trade names in Germany in parantheses) are the products on the market with the

Histrelin (Ortho)						D-His(Bzl)				Gly-NHEt
Triptorelin (Ferring)						D-Trp				

[a] Glp = pyroglutamic acid.

highest turnover. The Lupron line of products is the leading anticancer hormone drug with worldwide sales in 1996 of $ 810 × 10^6 followed by Zoladex with sales of $ 563 × 10^6.

Annual production is less than 100 kg for buserelin and significantly over 100 kg for the market leader, leuprorelin. At this order of magnitude, substances are only produced by classical organic preparative synthesis (fragment condensation in solution). Hoechst, for example, synthesizes the nonapeptide buserelin from the units pyroglutamic acid-histidine (Glp-His), tryptophan-serine-tyrosine (Trp-Ser-Tyr), and D-Serine-tert-butyl ether-leucine-arginine-proline-NHEt (D-Ser(*t*Bu)-Leu-Arg-Pro-NHEt); the tri- and tetrapeptide units are coupled to form the corresponding *C*-terminal heptapeptide, and then the *N*-terminal dipeptide is condensed with this to form the complete sequence. Control of the physicochemical process parameters, such as concentrations, precipitation, separations, reaction temperature profiles, and purification techniques, is important for successful scale-up of peptide synthesis to a technical scale [617].

9.4.1.1. Leuprorelin Acetate

Because leuprorelin inhibits the synthesis of androgen and estrogen, the drug blocks the growth of hormone-dependent tumors by shutting down testosterone production. Leuprorelin is indicated for the treatment of advanced prostate cancer, as an alternative to castration

for the treatment of endometriosis, and for the presurgical management of patients with anemia caused by benign fibroid tumors.

Trade name: Lupron (Abbott, Takeda).

9.4.1.2. Goserelin

As certain prostate tumors grow in response to testosterone, goserelin prevents the production of testosterone in testes and is therefore indicated for the treatment of prostate cancer, advanced breast cancer, and endometriosis.

Trade name: Zoladex (Zeneca).

9.4.2. LHRH Antagonists

Common to the intrinsic activity of all superagonists is the initial temporary stimulation of gonadotropin release. Soon after the use of highly active agonists became an established therapy, a search began for corresponding antagonists, which do not bring about an initial hormone release, to avoid this therapeutically counterproductive effect. A final big hurdle for clinical use of highly active antagonists was the inherent anaphylactic potential of these peptides. Starting from the sequence of native LHRH, the individual positions of the peptide chain were examined in rapid succession for their contribution to biological activity. Particular attention was paid to side effects. The most effective early improvements in antagonistic activity were achieved by using D-phenylalanine (D-Phe) instead of histidine at position 2, by D-amino acids at position 6 instead of Gly, and the exchange of *C*-terminal glycine for D-alanine (D-Ala^{10}). Further stepwise optimization led to the sequence scheme now usual for all modern antagonists of D-Nal^{1}-D-Cpa^{2}-D-Pal^{3} (Nal = 2-naphthylalanine, Cpa = Phe(4-Cl), Pal = 3-pyridylalanine) as hydrophobic cluster, a D-configured aromatic or aliphatic, yet hydrophilic, aminocarboxylic acid at position 6, and the *C*-terminal hydrophilic sequence Xxx^{8}-Pro^{9}-D-Ala^{10} where Xxx is either arginine or isopropyllysine. Excellent documentation of the stepwise optimization can be found in [618], [619].

Antagonists of the second generation caused formation of temporary edemas of the face and extremities in animal experiments, due in part to massive histamine release by mast cell degranulation. Cyanosis and respiratory impairment were also observed [620]. The cause of these intolerable side effects is thought to be the combination of D-arginine at position 6 with the three aromatic amino acids at the N-terminus of the sequence [621]. For the desired biological antagonist potency, a D-configured basic amino acid is necessary at position 6. A. V. Schally et al. achieved the breakthrough to highly active antagonists free of side effects with the derivatives SB-75 (cetrorelix) [*120287-85-6*] and SB-88 [*120287-93-6*], by incorporating hydrophilic, nonbasic amino acids with side-chain carbamoyl functions at position 6 (D-Citrulline^{6}, D-homocitrueline) [621], [622].

Today, e.g., cetrorelix is *manufactured* exclusively by classical fragment condensation on a kilogram scale. Two synthesis strategies proceed via either the *N*-terminal tripeptide (D-Nal^{1}-D-Cpa^{2}-D-Pal^{3}) or the *C*-terminal tripeptide (Arg^{8}-Pro^{9}-D-Ala^{10}) and the complementary heptapeptide (Ser^{4}-D-Ala^{10}) or (Nal^{1}-Leu^{7}) to the protected decapeptide with *tert*-butyl side chain protection. The deprotection with hydrochloric acid is followed by final purification by preparative HPLC. The *C*- and *N*-terminal functionalization of the acetylated decapeptide amide, necessary for biological activity and to avoid rapid enzymatic degradation, is introduced at the level of the terminal tripeptide. Functionalization is achieved by acetylation of the free α-amino group of naphthylalanine^{1} with acetylhydroxysuccinimide, or amminolysis of the resulting alanine^{10} methyl ester in alcoholic ammonia [623].

Folkers et al. were able to improve active antagonists successively by consistent and systematic modifications both at the relevant sequence positions and the side chain substituents; the most successful were complex substitutions at the positions 5, 6 and, in part, 8 [624–628]. An important contribution was made by Rivier et al., who synthesized the decapeptide "azaline" with novel modifications at positions 5 and 6, where aminotriazole-substituted *p*-aminophenylalanine or lysine are positioned [629–631]. Azaline B [*134457-28-6*] is probably one of the most active antagonists presently available worldwide.

DEGHENGHI published a highly active decapeptide sequence with minimal histamine release and good water solubility. This structure, known as antarelix [*151277-78-5*], differs from SB-75 (cetrorelix) in that it has homocitrulline^6 instead of citrulline^6 and isopropylysine^8 instead of arginine^8 [633]. By using Lys(*i*Pr)^8, residual potential for histamine release can be further reduced. Organon is developing the antagonist ganirelix (RS26306) [*124904-93-4*] under license from Syntex; this is a decapeptide with novel alkyl-modified D- and L-homoarginine units at positions 6 and 8 [634]. With ramorelix (HOE 013) [*127932-90-5*], Hoechst (HMR) has a peptide antagonist with a sugar – amino acid unit (*O*-α-L-rhamnosyl-D-serine^6), that has improved water solubility [632]. Schering has also synthesized peptide antagonists, using nonproteinogenic amino acids, such as ε-dialkylated lysine or benzodiazepine aminocarboxylic acids [635], [636]. Abbott's A-76154 [*136989-30-5*] is an octapeptide antagonist with LHRH receptor affinity of a similar order of magnitude to that of active decapeptides such as A-75998 [*135215-95-1*] or "Nal-Glu" [*103733-02-4*] [644].

9.4.2.1. Receptor Assays

At present, selected peptides are being tested in vivo by measuring the testosterone concentration in male rat serum. Here, a single subcutaneous application of a potent LHRH antagonist leads to persistent testosterone suppression. The activity in animals generally correlates well with the binding affinity determined in vitro on human receptors. In cases where no in vivo activity was observed despite high binding affinity, the peptide probably had pharmacokinetic characteristics that played a decisive role. In the future, transgenic animals will also be very important for in vivo testing [645–647].

9.4.2.2. Peptidomimetics

For some years, increased efforts have also been made to find substances with affinity to the LHRH receptor that do not have the characteristic substance-specific properties and also disadvantages of peptides (short half-life, lack of bioavailability), yet have a high binding affinity. Ideally, such substances should be able to be administered orally, be sufficiently stable in the organism, and possess favorable pharmacological parameters comparable to peptide antagonists. Clinical investigations of the influence of the antimycotic ketoconazole on prostate cancer and testosterone suppression indicate that it may have a LHRH-mimetic effect [648], [649]. Further investigations by Abbott showed weak antagonistic activity both in vitro and in vivo for ketoconazole and its modified analogs; however, the biological activity of such derivatives is most probably not mediated mainly by LHRH antagonism [650], [651]. Complex, highly substituted nitrogen heterocycles seem to have LHRH antagonistic potential [652]. In patent literature benzodiazepines, benzodiazepinones, heterocyclic benzo-substituted alkylamines, and thienopyridine carboxylic acid derivatives are described as LHRH receptor antagonists with receptor-binding inhibition at submicromolar concentrations, suitable amongst other uses as antitumor agents for hormone-dependent tumors [647], [653]. A lead structure from the latter substance class is in extensive pharmacological trials [654–656].

10. Signal Transduction Inhibitors

Anticancer drug discovery has been directed away from agents that affect cells by producing DNA damage towards modulators of signal transduction pathways that have become unregulated or aberrant in malignant transformation [657].

10.1. Enzyme Inhibitors

Binding of growth factors [658], such as epidermal growth factor (EGF) [659] to a membrane bound receptor tyrosine kinase results in dimerization and autophosphorylation of tyrosine residues on the protein surface. As result the GTP-bound form of *ras* (→ Toxicology, Chap. 3.7.3.1.) [660] undergoes a conformational change on its surface, enabling it to bind to several effector molecules leading to the activation of transcription factors involved in DNA synthesis [661]. An overexpression of the EGF-receptor is observed in various types of human cancers.

Mechanism-based screens have identified the natural products bryostatin [662] [*83314-01-6*] as partial agonist of protein kinase C and fumagillin [663] [*23110-15-8*] as interfering with tumor-induced neovascularization thus inhibiting angiogenesis. FR-111142 as analog of fumagillin is reported to be less toxic and more active than the parent compound [664]. A potent inhibitor of *ras* protein farnesylation [665] is pepticinnamin E [666], and peptides related to the CAAX-tetrapeptide (where C is cysteine, A is valine, isoleucine, or leucine, and X is methionine or serine). In order to prepare completely nonpeptide and potentially more stable inhibitors a series of potent peptidomimetic inhibitors were designed [667].

Specific natural and synthetic kinase inhibitors are in clinical development as anticancer agents [668–670].

Bryostatin 1

10.2. Phospholipid – Based Antineoplastics

Ether phospholipids and lysophospholipids are naturally occurring derivatives of phospholipids of the cell membrane with many interesting properties. For example, the ether phospholipid 1-*O*-alkyl-2-acetyl-sn-glycero-3-phosphocholine (platelet activating factor, PAF) [671] causes platelet aggregation and dilation of blood vessels and lysophosphatidic acid (LPA), the simplest natural phospholipid, is a potent mitogen. The observation that alkyllysophospholipids exerted experimental antitumor activity in vitro and in vivo [672], [673] led to systematic modification of the structures and subsequent clinical investigation of, e.g., ilmofosine [*83519-04-4*] [675]. In the course of modification it was found that an analog without glycerol backbone was equally effective.

Miltefosine (D-18506, hexadecylphosphocholine), [*058066-85-6*] [676], 2-[[(hexadecyloxy)-hydroxyphosphinyl]oxy]-*N,N,N*-trimethylethanaminium hydroxide (inner salt); $C_{21}H_{46}NO_4P$, M_r 407.57 is a new phospholipid-based antineoplastic agent which

exerts substantial antitumor activity in appropriate models. Because of its special pharmacology – high activity against mammary carcinoma and low toxicity to normal tissue – it is an ideal candidate for topical treatment of cutanous breast cancer metastases. The substance was launched in 1993 as a topical formulation for palliative treatment of refractory skin metastases of breast cancer [676].

Trade name: Miltex (ASTA Medica).

A variety of derivatives were synthesized and characterized, some of which appeared to be considerably less toxic to the gastrointestinal tract [677]. One of them, perifosine (D-21266) [*157716-52-4*] is currently in clinical trials.

Mechanism of Action. Miltefosine shows highly selective antineoplastic activity in DMBA- and *N*-methyl-*N*-nitrosourea (MNU)-mammary carcinoma of the rat. The activity is not due to an antiestrogenic effect in these estrogen-dependent tumor models [678]. The treatment was tolerated and no overt toxic symptoms were observed. The mechanism of action of miltefosine is most probably different from that of other chemotherapeutic agents [679]. Incorporation of miltefosine and metabolites into biological membranes was demonstrated, affecting the interactions of receptor proteins or membrane associated enzymes involved in growth control and cellular signalling [680]. The reduction in tumor mass was accompanied by morphological changes compatible with the induction of differentiation [675], [681]. Furthermore, the decrease of tumors was mainly due to cell loss by apoptosis.

Ilmofosine

Miltefosine

In clinical trials mild dryness and flaking of the skin were noted, but no systemic toxicity was reported after topical administration. Several phase I and II studies in patients that were treated with oral capsules were terminated early due to gastrointestinal intolerance [682].

11. Economic Aspects

The world cancer drug market is expected to reach $ 14 × 10^9 by 2000 [10], [14]. Total sales of the top 100 anticancer drugs generated a turnover of $ 4.66 × 10^9 in 1996. Of the worlds eight top-selling anticancer drugs, four – the prostate cancer-drugs flutamide (Eulexin), bicalutamide (Casodex), leuprorelin (Lupron) and goserelin (Zoladex) – are merely palliative, yet have combined annual sales of $ 1.7 × 10^9, whereas sales of the breast cancer drugs tamoxifen (Nolvadex) and paclitaxel (Taxol) are approaching $ 500 × 10^6 and $ 850 × 10^6, respectively.

Taxol, BMS's drug for treating ovarian and breast cancers, was the biggest selling anticancer agent in 1996, with sales of $ 813 × 10^6.

Candles

See also → Waxes, Chap. 4.7.

FRANZ WILLHÖFT, Rosengarten-Nenndorf, Federal Republic of Germany

RUDOLF HORN, Hamburg, Federal Republic of Germany page 2

Records show that candles were first used around the eighth century B.C.

Until about 1850, candles were made out of raw [*8006-40-4*] or bleached [*8012-89-3*] beeswax and animal fats (beef tallow). Spermaceti [*8002-23-1*], paraffin [*64742-43-4*], and stearin [*11099-07-3*] have since been added to the list of raw materials.

Raw Materials. The raw materials used in the production of candles can be classified as basic materials and additives.

Basic materials: paraffin, beeswax, stearin
Additives: microcrystalline waxes, hard waxes, opacifiers, coloring agents, and other such additives as polyethylene, resins, and perfumes

Refined paraffin, obtained from mineral oil and having a low oil content, is the principal raw material used today in the fabrication of candles (→ Waxes). It is a mixture of normal paraffins, isoparaffins, and cycloparaffins (naphthenes). The percentage of each component in the mixture depends on the type of crude oil and on the extent of refining prior to wax isolation. The *n*-paraffins shrink severely on solidification, and at temperatures below the solidification point they form relatively large, uniform crystals. The isoparaffins contract less on solidification than the *n*-paraffins and form smaller, less uniform crystals. The cycloparaffins, which can be composed of one or more rings and of branched or unbranched chains, usually solidify in an amorphous mass. Only a few form small, needle-shaped crystals.

Beeswax (→ Waxes) is a mixture which contains approximately 12 % *n*-paraffins in addition to hydrocarbon waxes, free fatty acids, cerotic acid [*506-46-7*], cerotic esters, and cholesteryl esters. It is plastic andhighly malleable, but it does not smear. It is hard and brittle under cold-conditions, an indication that the softening point and the melting point lie far apart on the temperature scale. Beeswax is used to produce wax sheets which are then processed into candle decorations and altar candles.

Stearin is used in pure form or in mixtures for candle making. It contains primarily palmitic acid [*57-10-3*] and stearic acid [*57-11-4*] (C_{16} and C_{18} fatty acids) and gives the candle an opaque, white, and very full appearance.

Microcrystalline waxes are hydrocarbon waxes with a very fine crystalline structure.

Hard waxes (→ Waxes) are either natural, particularly carnauba wax [*8015-86-9*], or synthetic products.Polymethylene [*68649-50-3*] (synthesized using the Fischer-Tropschtechnique) or polyethylene [*9002-88-4*] (obtained using the Zieglersynthesis) mainly are used. When added to the raw materials, they give candlesan opaque appearance, and in trace amounts they give a good hardness.

Opacifiers include stearin, hard waxes, polyethylenes, and, above all, organic and inorganic pigments. Air, blown into the wax material, also acts as an opacifier.

Candle material can be *colored* by adding either 0.1 – 0.8 % of an oil- or paraffin-based dye or about 0.5 – 2.0 % of a pigment to the basic materials.

Wick. The wick is made of braided cotton and can be either flat or round. Usually raw yarn is employed, hence the wick subsequently must be washed, bleached, prepared, spun, and dried. Ammonium salts (e.g., ammonium nitrate, ammonium phosphate, and ammonium sulfate), potassium chloride, potassium nitrate, borax, and boric acid prevent the wick from glowing after the candle has been put out. They regulate the state of the wick, ensure complete burning, and act as oxygen carriers. The wick controls the melting, evaporation, and burning of the candle

10.1002/14356007.a05_029

material. It conveys the liquid wax from the cup to the burning zone. The capillarity of the wick should be sufficient to enable the liquid wax to rise fast enough and yet not stream down the sides of the candle.

Manufacturing Technique. Although substantially improved models of the well-known candle molding or candle drawing machines are still available, a powder press (one- to eight-stanchion press) is normally used. The paraffin powder is so intensely compressed in a cylinder that at a compression of approximately 1.7 : 1 a solid, rough candle is formed. Methods used in the extrusion of plastics have also been applied to the processing of wax; in no other method used in the manufacture of candles are the demands on the raw materials so critical. The granules are pressed through a cylinder by means of a screw conveyer and subsequently forced through a perforated disc into a slightly constrictive compression chamber. The end of the machine is joined to a small, heated, cylindrical tube from which a ribbon of the still malleable candle continuously issues.

In the latest method employing a horizontal piston press, the granules (powder, chunks, beads) are fed into the press and compressed with each cycle of a hydraulic piston. The cycle time and throughput are variable. The candle appears discontinuously through the bore that determines its diameter.

The wick can also be dipped into the wax melt using special machines and the process repeated until the candle acquires the required diameter. The appearance of rough candles produced in this manner can subsequently be improved by dipping them into a coloring bath.

Economic Aspects. The production of candles in the Federal Republic of Germany increased from 8 kt in 1955 to 46.5 kt in 1983. The per capita consumption in 1983 was almost 1 kg.

The candle production in Western Europe in 1979 amounted to 165 kt; per capita consumption was about 430 g. The production in the United States in 1979 was 100 kt.

1. History

ε-Caprolactam (2-oxohexamethylenimine, hexahydro-1*H*-azepin-2-one) has been known since the 19th century. S. GABRIEL and T. A. MAAS synthesized caprolactam in 1899 by cyclization of ε-aminocaproic acid. O. WALLACH synthesized caprolactam by Beckmann rearrangement of cyclohexanone oxime. Commercial interest increased in 1938, when P. SCHLACK of IG Farbenindustrie produced the first spinnable polymer by polycondensation of caprolactam. Since then, caprolactam has gained importance. Large-scale industrial production has increased rapidly. In 1989, world production reached ca. 2×10^6 t, in 1994 ca. 2.2×10^6 t [8].

Caprolactam is soluble in polar and aromatic solvents and slightly soluble in high molecular mass aliphatic hydrocarbons. The solubility of caprolactam in various solvents is summarized in Table 1.

3. Chemical Properties

Polymerization is caprolactam's most important chemical property. The ring is hydrolyzed at 260 – 270 °C. Linear polymer chains are formed by polycondensation [9]. Caprolactam also reacts directly by polyaddition with the polymer chains. These reactions lead to an equilibrium between the polymer and caprolactam favoring a 90 % conversion to polymer. Caprolactam can also be polymerized by anionic polymerization at low moisture contents, preferably less than 100 ppm. A catalyst and cocatalyst system is necessary. The reaction temperature is lower than in hydrolytic polymerization.

Caprolactam can undergo all cyclic amide reactions, such as oxidation, hydrolysis, *N*-alkylation, phosphogenation, and nitration.

Molten caprolactam absorbs atmospheric oxygen. Oxygen reacts at 75 °C with caprolactam to produce very small amounts of peroxide. Above 100 °C adipic acid imide is formed [10].

This reaction is catalyzed by traces of heavy metals.

Caprolactam is heat stable in the absence of oxygen [11].

Caprolactam is quantitatively converted to ε-aminocaproic acid by hydrolysis with aqueous acids or alkalis [12]. Treatment with gaseous methanol in the presence of a dehydrating catalyst gives *N*-methyl-ε-caprolactam, a versatile solvent [13]. Caprolactam reacts with phosgene to give chloroformic acid ε-caprolactim ester. Nitration gives nitrocaprolactam, and subsequent reduction amino-caprolactam. L-Lysine is formed from amino-caprolactam by hydrolysis and resolution of the racemate [14]. Reactions with other chemical reagents are of no industrial importance.

4. Production

Many methods for caprolactam production have been developed. All commercial processes are based on benzene or toluene from BTX extract streams. Figure 1 summarizes the various processes.

Large-scale industrial processes are, without exception, multistage processes in which ammonium sulfate and sometimes organic compounds are formed as byproducts.

Cost-efficiency depends a great deal on the byproducts. Large quantities of ammonium sulfate are undesirable in the manufacture of caprolactam. The profitability of a process is dependent on this.

Large-scale industrial processes employ cyclohexanone, cyclohexane, or toluene as starting materials.

About 90 % of the caprolactam is produced by using the conventional cyclohexanone process. Cyclohexanone is obtained by catalytic oxidation of cyclohexane with air, or by hydro-

Figure 1. Routes to caprolactam

genation of phenol and dehydrogenation of the cyclohexanol byproduct. The conversion of cyclohexanone to cyclohexanone oxime followed by Beckmann rearrangement gives caprolactam. The yield from cyclohexanone approaches 98 %.

About 10 % of caprolactam is produced by photonitrosation of cyclohexane or by nitrosation of cyclohexanecarboxylic acid in the presence of sulfuric acid; in the latter process cyclohexanecarboxylic acid is produced from toluene.

4.1. Processes via Cyclohexanone

4.1.1. Cyclohexanone Oxime

In caprolactam processes using cyclohexanone, water containing cyclohexanone oxime is formed and isolated as an intermediate.

Physical Properties. Cyclohexanone oxime is a white crystal with a slightly pungent odor. Typical properties are listed below:

Cyclohexanone oxime can be distilled without decomposition only under reduced pressure. For unknown reasons, violent decomposition may occur [15]. Traces of acid can initiate spontaneous rearrangement.

Chemical Properties. The Beckmann rearrangement to caprolactam is the most important industrially used reaction. The catalytic reduction of cyclohexanone oxime with hydrogen gives cyclohexylhydroxylamine and cyclohexylamine [15]. Hydrolysis with mineral acids gives cyclohexanone and the corresponding hydroxylamine salt.

Production. The reaction of cyclohexanone with hydroxylamine is the best known method for the production of cyclohexanone oxime.

Hydroxylamine is used in its sulfate or phosphate form.

Some manufacturers produce hydroxylamine by the modified Raschig process using ammonium salts as starting materials. Oximation is then carried out with aqueous hydroxylammonium sulfate solution containing ammonium sulfate. The sulfuric acid liberated is neutralized with ammonia to form ammonium sulfate. The amount of ammonium sulfate formed during oximation is about 2.7 tons per ton of cyclohexanone oxime [16].

The BASF process (Fig. 2) for the production of hydroxylammonium sulfate solution generates about 0.7 tons of ammonium sulfate per ton of cyclohexanone oxime during the oximation step. A similar process has been developed by Inventa [17]. BASF and Inventa obtain the hydroxylammonium sulfate solution by hydrogenation of nitric oxide over a platinum catalyst in the presence of dilute sulfuric acid. The hydroxylammonium sulfate solution is reacted with cyclohexanone and ammonia in an oxime reactor.

This reaction is conducted with thorough mixing at 85 – 90 °C in a weak acidic solution.

Cyclohexanone oxime is obtained as a moist melt. It is separated from the aqueous ammonium sulfate solution in a separator drum. The purified aqueous ammonium sulfate solution is free of substances that would be undesirable in fertilizer- or technical-grade salt uses.

4.1.2. Beckmann Rearrangement to Caprolactam

All caprolactam manufacturers use sulfuric acid or oleum as a rearrangement medium. The rearrangement is more complete in concentrated sulfuric acid. Excess sulfur trioxide further increases the speed of the rearrangement [18].

The rearrangement, which includes opening of the cyclohexyl ring, is a very rapid, highly exothermic reaction.

Since the Beckmann rearrangement is highly exothermic, molten cyclohexanone oxime and concentrated oleum (27 %) are introduced simultaneously into a relatively large amount of already rearranged product.

Molar ratios of cyclohexanone oxime and oleum may range from 1 to 1.05 [19]. Sulfur trioxide binds the water in the moist cyclohexanone oxime to form sulfuric acid and catalyzes the rearrangement. Cooling reduces the heat of reaction. The reaction gives the sulfate of caprolactam in excess sulfuric acid. It is hydrolyzed by neutralization with ammonia or ammonia water. The reactions take place according to the following equations:

Figure 2. BASF caprolactam production
a) Oximation; b) Oxime separation; c) Rearrangement; d) Neutralization; e) Crude-lactam separation; f) Extraction; g) Crystallization; h) Centrifuge; i) Solvent distillation; k) Lactam distillation

The rearrangement mixture is removed from the reactor at the rate it is formed. It is neutralized in ammonia and water to prevent precipitation of solid ammonium sulfate. The reaction product is then separated from the lighter phase above the concentrated ammonium sulfate solution as 70 % aqueous crude caprolactam. The crude caprolactam is removed in a separator drum and fed to an extractor.

Caprolactam is extracted with solvents such as benzene, toluene [20], or chlorinated hydrocarbons. The virtually caprolactam-free aqueous solution is discharged into a waste treatment plant or incinerated.

Concentrated ammonium sulfate solution is further evaporated and crystallized.

The caprolactam-containing solvent is fed into a distillation column. Solvent-free caprolactam is further distilled under reduced pressure. Very pure caprolactam is obtained in molten form. It is either used as such or solidified in a flaker. A total of 4.5 tons of ammonium sulfate per ton of caprolactam is obtained from both oximation and neutralization with the Raschig process. The BASF or Inventa process produces a total of 2.5 tons of ammonium sulfate per ton of caprolactam in oximation and neutralization.

Caprolactam yields can be improved and undesirable byproduct formation reduced by multistage rearrangement and the adjustment of reaction conditions in each stage. Acid concentration, free sulfur trioxide concentration, amount of oxime added, reaction temperature, and degree of mixing are critical variables at each stage [21].

Some processes differ from the BASF process with regard to purification of crude caprolactam.

In the Allied Chemical process, solvent extraction is followed by crystallization from aqueous caprolactam solution.

In the DSM process, the crude caprolactam is first extracted with a solvent and then reextracted with water. Before being distilled, the caprolactam extract is subjected to a number of physicochemical purifications, such as hydrogenation and ion exchange treatment [17].

Polimex developed a different approach by combining crystallization from aqueous caprolactam solution and oxidizing treatment. This

physical and chemical purification process is followed by distillation [22].

Inventa licenses caprolactam plants that utilize crystallization as a final purification process.

4.1.3. Improvement of the Oximation Process

Oximation processes which form no or little ammonium sulfate have been developed by DSM [23], [24] and BASF [25]. These processes comprise a combination of hydroxylamine and oxime manufacture.

Hydroxylamine–Phosphate Oxime Process (HPO Process of DSM; Fig. 3) The process proceeds according to the following equation:

Oximation is conducted in a hydroxylamine phosphoric acid buffer solution. After separation of the oxime, the remaining aqueous ammonium phosphate buffer solution is recycled to hydroxylamine synthesis and concentrated. The reactions involved are described below:

1) Reduction of the phosphoric acid/ammonium nitrate buffer solution with hydrogen, and formation of hydroxylammonium phosphate:

$$NH_4NO_3 + 2\ H_3PO_4 + 3\ H_2 \longrightarrow$$
$$[NH_3OH]^+\ [H_2PO_4]^- + NH_4H_2PO_4 + 2\ H_2O$$

Palladium on graphite or alumina carrier is used as a catalyst.

2) Oxime formation:

3) After the oxime has been separated, the nitrate ions consumed are replaced by addition of 60 % nitric acid.

$$H_3PO_4 + NH_4H_2PO_4 + 3\ H_2O + HNO_3 \longrightarrow$$
$$2\ H_3PO_4 + NH_4NO_3 + 3\ H_2O$$

The hydroxylamine formed by catalytic hydrogenation of nitrate ions reacts with free phosphoric acid in the buffer solution at pH 1.8 to form a hydroxylammonium phosphate solution. The reaction takes place in special columns; the unreacted hydrogen is separated from the catalyst suspension in a separator, and is recycled to the reaction via a compressor.

After the catalyst has been filtered and recycled, the hydroxylamine buffer solution reacts with cyclohexanone in the oximation reactor to produce cyclohexanone oxime. Toluene is used as the solvent and phosphoric acid is liberated.

Oximation takes place in a cascade of mixers and separators with a countercurrent process at pH 2. Conversion is 98 %.

The remaining 2 % of unreacted cyclohexanone is oximated at pH 4.5 with about 3 % of the mainstream hydroxylamine. Ammonia is added. The toluene, containing about 30 % oxime, is separated from the aqueous buffer solution. The cyclohexanone oxime is freed from toluene and fed into the Beckmann rearrangement process. The distilled solvent is recycled to the oximation process [26]. To avoid poisoning of the catalyst, residual cyclohexanone and oxime are extracted from the separated buffer solution. Toluene is used as the extracting agent and the process is carried out in a packed pulsed column. The exhausted buffer solution still contains dissolved toluene, which is stripped with steam. In addition, the excess ammonium ions formed as a reduction byproduct in the buffer solution must be removed. This is achieved with nitrous gases from the combustion of ammonia. This reaction proceeds according to the following equation:

$$2\ NH_4H_2PO_4 + NO + NO_2 \longrightarrow 2\ N_2 + 3\ H_2O + 2\ H_3PO_4$$

The reaction takes place in a decomposition column, and the nitrogen generated passes into the vent gas. The excess nitrogen oxides are absorbed in a downstream column and recycled for hydroxylamine synthesis.

Oximation without Neutralization or Acidic Oximation (BASF). The reactions involved are summarized by the following basic formula [25]:

Figure 3. DSM HPO hydroxylamine and cyclohexanone oxime production
a) Compressor; b) Hydroxylamine generator; c) Separation; d) Filtration; e) Oximation; f) Neutralization; g) Solvent distillation; h) Extraction; i) Toluene stripping; k) Ammonia combustion; l) Condenser; m) Decomposition and absorption column

1) Nitric oxide is catalytically hydrogenated in an ammonium hydrogen sulfate solution:

$$NO + 3/2\ H_2 + (NH_4)HSO_4 \longrightarrow (NH_3OH)(NH_4)SO_4$$

Platinum on graphite is used as catalyst.

2) Cyclohexanone oxime is formed by reacting cyclohexanone with ammonium hydroxylammonium sulfate:

Whereas the sulfuric acid set free in BASF's classic process is neutralized with ammonia for separation of cyclohexanone oxime, further neutralization of ammonium hydrogen sulfate is not required for cyclohexanone oxime recovery. Hence, the ammonium hydrogen sulfate is recycled directly into hydroxylamine production (Fig. 4).

After filtration and separation of the catalyst, the ammonium hydroxylammonium sulfate solution is fed into the oximation process. Oximation takes place in a special column by means of countercurrent flow of cyclohexanone and hydroxylamine solution with 97 – 98 % conversion.

Temperature is maintained above the melting point of cyclohexanone oxime.

Complete conversion of cyclohexanone is achieved with classic after-oximation.

Some ammonium sulfate is produced was by-product in both hydroxylamine synthesis and after-oximation. The ammonium level can be kept constant with a purge to after-oximation. The corresponding sulfate deficit is made up by addition of sulfuric acid.

The aqueous phase of oximation contains ammonium hydrogen sulfate as well as traces of cyclohexanone and cyclohexanone oxime. The recycled ammonium hydrogen sulfate solution must be free of residual carbon. This is achieved in a stripping tower, where residual cyclohexanone oxime is decomposed and cyclohexanone stripped. The resulting ammonium hydrogen sulfate solution is virtually free of organic material and recycled to hydroxylamine production.

Acidic oximation gives 0.1 ton ammonium sulfate per ton of cyclohexanone oxime.

Figure 4. BASF acidic oximation
a) Oximation; b) After-oximation; c) Ammonium purge; d) Stripping column

4.1.4. Gas-Phase or Catalytic Rearrangement of Cyclohexanone Oxime

Interest in heterogeneous catalytic rearrangement of cyclohexanone oxime was prompted by economic considerations in order to avoid the ammonium sulfate generated in Beckmann rearrangement.

In 1938, Du Pont proposed a process in which the cyclohexanone oxime vapors are passed over water-eliminating catalysts such as oxides of silicon, aluminum, titanium, or magnesium, preferably in the presence of ammonia, under atmospheric or reduced pressure at 250 – 350 °C.

In the early 1950s, Leuna-Werke demonstrated surface catalysis [27]. This work led to worldwide activity on catalytic rearrangement by such companies as BASF, Bayer, Solvay, BP Chemicals, Mitsubishi, Asahi, and Honshu.

An additional catalytic rearrangement process was developed in the former States of the USSR.

Figure 5 shows the process developed and proven by BASF in a large-scale pilot plant. The catalyst system contains boric acid. It is advantageous to have the catalyst in a fluidized bed during reaction and regeneration. A fluidized flow system is also possible [28].

Figure 5. Catalytic oxime rearrangement
a) Fluidized-bed reactor; b) Catalyst regenerator; c) Cyclone; d) Cyclone; e) Condensation; f) Pre-evaporation

The catalyst can be transported by means of a pneumatic conveyor from the fluidized-bed reactor to the catalyst regenerator and back. In the catalyst regenerator, the catalyst is regenerated with air at 700 – 900 °C [28–30]. Dust is removed from the stack gases in a cyclone. The catalyst can be cooled to the reaction temperature before recycling.

The fluidized-bed reactor can be operated under atmospheric, reduced, or elevated pressure by introducing a certain amount of inert gas as a fluidizing agent to the bottom of the reactor.

The cyclohexanone oxime can be injected into the 275 – 375 °C fluidized bed as a gas or liquid via nozzles. It can be introduced as a solid with the aid of an inert-gas stream [31–33]. The pre-evaporation of cyclohexanone oxime is particularly advantageous.

The recovery of rearrangement heat supplies the heat of fusion and evaporation.

Catalyst dust deposited in the cyclone can be reused for the production of fresh catalyst. The

hot vapors from the cyclone can be condensed on a surface condenser or in a column [34]. The inert gas required for fluidization can be circulated. Crude caprolactam obtained by catalytic rearrangement (yield up to 96 %, based on cyclohexanone oxime) is less pure and the impurities are different from those in caprolactam produced by Beckmann rearrangement. It is therefore purified by combined extraction, crystallization, and distillation methods, as described in references [35–45].

However, caprolactam has not yet been produced catalytically on an industrial scale.

4.1.5. Modified Oximation and Beckmann Rearrangement

It has been proposed that cyclohexanone be reacted with hydroxylammonium nitrate instead of hydroxylammonium sulfate. In this case, ammonium nitrate is formed as byproduct in oximation [46].

Another process bypasses ammonium salts as byproducts in oximation. The acid obtained during the reaction of cyclohexanone with hydroxylammonium salts is removed by electrodialysis [47].

The Beckmann rearrangement of cyclohexanone oxime can be carried out in polyphosphoric acid [48] instead of oleum. The rearrangement mixture is neutralized in an organic solvent in which caprolactam and polyphosphoric acid are soluble. The monoammonium dihydrogen phosphate and diammonium monohydrogen phosphate formed during neutralization with ammonia are separated.

It has also been proposed that the rearrangement of cyclohexanone oxime be carried out in acetic acid over acidic ion exchangers [49]. Mixtures of oleum and phosphoric acid, sulfur trioxide in liquid sulfur dioxide, thionyl chloride, phosgene, hydrofluoric acid in acetic anhydride, and chlorosulfonic acid in chlorinated hydrocarbons can also be used [50].

Attempts have been made to neutralize the mixture obtained from rearrangement in oleum with metal oxides, such as calcium oxide, instead of ammonia [51]. It is proposed that the resulting calcium sulfate is then decomposed thermally into recyclable calcium oxide and sulfur dioxide. Diluting the rearrangement reaction mixture with water and extracting the caprolactam with a solvent such as phenol is another method for avoiding the production of ammonium sulfate [52].

Another approach is to dilute the rearrangement mixture with aqueous ammonium sulfate or ammonium dihydrogen phosphate resulting in splitting caprolactam sulfate into caprolactam and sulfuric acid and then extracting caprolactam [53]. The resulting sulfuric acid solution containing ammonium salts is used in phosphoric acid production. It has been proposed for economic reasons to decompose ammonium sulfate from rearrangement back into ammonia and sulfur dioxide containing gas streams [54].

4.2. Photooximation

In the 1950s, Toray industries developed a photochemical process for the production of caprolactam (Fig. 6).

Photonitrosation (PNC) converts cyclohexane to cyclohexanone oxime dihydrochloride followed by Beckmann rearrangement.

The cyclohexane is reacted with nitrosyl chloride to give cyclohexanone oxime hydrochloride:

1) Preparation of nitrosylsulfuric acid from nitrous gases obtained from combustion of ammonia, and sulfuric acid:

$$2\ H_2SO_4 + NO + NO_2 \longrightarrow 2\ NOHSO_4 + H_2O$$

2) Preparation of nitrosyl chloride by reaction with hydrogen chloride:

$$NOHSO_4 + HCl \longrightarrow NOCl + H_2SO_4$$

3) Photochemical reaction:

The industrial photonitrosation process is based on the development of efficient photoreactors. Toray designed an immersion lamp with a high radiation efficiency and capacity as well as long life. In order to remove the short-wave radiation below 365 nm, which contributes to tar formation on the lamps, either an absorbent is

Figure 6. Toray PNC caprolactam production

added to the cooling water, or the light source is surrounded by a glass filter [55].

The cyclohexanone oxime produced by photonitrosation of cyclohexane is separated as the dihydrochloride in the presence of excess hydrogen chloride. This compound exists in the form of oil droplets and forms a heavier lower phase in cyclohexane; this lower phase is subjected to Beckmann rearrangement with excess sulfuric acid or oleum to give caprolactam. Hydrogen chloride is set free and recycled. The rearrangement reaction mixture is neutralized with ammonia water to give crude lactam and ammonium sulfate.

PNC process description: Nitrous gases are produced in an ammonia burner and cooled. They then react with sulfuric acid to form nitrosylsulfuric acid. This is brought into contact with excess hydrogen chloride to give nitrosyl chloride. The remaining sulfuric acid is dehydrated and then either recycled into the nitrosyl chloride production stage, or circulated. The gaseous nitrosyl chloride/hydrogen chloride mixture is passed through liquid cyclohexane. The conversion to oxime dihydrochloride is carried out in a photoreactor with actinic light from cooled mercury immersion lamps. This product separates at the bottom as a heavy oil. In order to prevent the deposit of oxime salt and resinous coating, the walls of the lamp cooler are periodically washed with concentrated sulfuric acid [56]. The thermal energy emitted from the light source must be removed by cooling water. Since nitrosyl chloride, hydrogen chloride, and oxime dihydrochloride are extremely corrosive, the photoreactor is made of titanium [57] or lined with enamel or PVC.

Unreacted nitrosyl chloride is removed from the photoreactor with the excess hydrogen chloride and recycled into the photochemical reaction. The oily oxime dihydrochloride is then rearranged with oleum. Unreacted cyclohexane is purified during cyclohexane regeneration and reused. Hydrogen chloride is liberated during

Beckmann rearrangement if carried out under the same conditions as with pure oxime which is then absorbed during the hydrogen chloride regeneration stage in dilute hydrochloric acid. The solution is concentrated in the hydrogen chloride recovery stage and recycled into nitrosyl chloride production. The mixture from the rearrangement reaction is neutralized with ammonia water and the aqueous crude caprolactam is purified. This includes a chemical process, drying, and distillation. In cyclohexane regeneration, a small chlorocyclohexane residue is obtained. The ammonium sulfate solution is crystallized by evaporation. In the PNC Toray process, 1.55 tons of ammonium sulfate are produced per ton of caprolactam [58].

4.3. Production from Toluene

Snia Viscosa developed a toluene-based process in 1960 [59](Fig. 7).

Caprolactam is obtained in three steps:

1) Catalytic oxidation of toluene with air to benzoic acid:

2) Hydrogenation of benzoic acid to cyclohexanecarboxylic acid:

3) Nitrosodecarboxylation of cyclohexanecarboxylic acid to caprolactam in the presence of oleum:

During the last stage, nitrosocyclohexane and cyclohexanone oxime are formed in situ. Cyclohexanone oxime immediately undergoes rearrangement to caprolactam.

Snia process description: The oxidation of toluene with air is carried out in liquid phase using a cobalt catalyst at 160 – 170 °C and 0.8 – 1 MPa (8 – 10 bar) pressure. The yield is well above 90 % of theory. The gases from the oxidation reactor contain mainly nitrogen with small amounts of oxygen, carbon dioxide and carbon monoxide. They are cooled to 7 – 8 °C in order to recover unreacted toluene. The water accumulated during the reaction is removed in a separator drum and toluene is recycled to the reactor. In addition to toluene and cobalt catalyst, the liquid reaction product contains about 30 % benzoic acid and also various intermediates and byproducts.

Most of the toluene is removed by distillation, and the remaining concentrated solution is given into a rectification column. The lower-boiling intermediates and the remaining toluene are removed at the top and reused. Benzoic acid in vapor form is removed from the rectification column as a side stream. The high-boiling byproducts leave the column as a residue. They include the cobalt salt, which is reprocessed. The benzoic acid obtained is suitable for hydrogenation without any further purification.

Hydrogenation of benzoic acid to cyclohexanecarboxylic acid is carried out in liquid phase in the presence of a palladium on graphite catalyst. A series of stirred reactors are used with a temperature of about 170 °C and pressure of 1 – 1.7 MPa (10 – 17 bar). Conversion is 99.9 % with a commensurate yield. The catalyst is centrifugally separated from the liquid reaction product, mixed with benzoic acid, and reused in hydrogenation. Cyclohexanecarboxylic acid is distilled under reduced pressure. Any catalyst still present remains in the residue. A 73 % nitrosylsulfuric acid solution in sulfuric acid is used for the nitrosation of cyclohexanecarboxylic acid. It is obtained by absorption of nitrous gases (from ammonia combustion) in concentrated sulfuric acid or oleum. Cyclohexanecarboxylic acid is premixed with oleum at ambient temperature and fed into a multistage nitrosation reactor. Exactly defined amounts of cyclohexanecarboxylic acid and nitrosylsulfuric acid are reacted at each stage, ensuring the complete reaction of the nitrosating agent. The conversion rate of the cyclohexanecarboxylic acid is maintained at about 50 %. One mole of carbon dioxide per mole of caprolactam is set free along with small amounts of other gases such as nitric oxide, carbon monoxide, sulfur dioxide, and nitrogen. In order to maintain the reaction and remove the reaction heat, this process

Figure 7. SNIA caprolactam production

is carried out in boiling cyclohexane under atmospheric pressure. Depending on the organic acid, less than 10 % of the yield is lost.

Sulfonic acids are byproducts. During the reaction, 3.3 moles of sulfuric acid per mole of caprolactam are consumed. Nitrosation with subsequent rearrangement is the most important part of the process [60].

Products from the nitrosation/rearrangement step are hydrolyzed with water at low temperatures. Cyclohexane extracts unreacted cyclohexanecarboxylic acid. The final residues are extracted from the sulfuric acid solution, which has been diluted with water, by countercurrent extraction using cyclohexane as the solvent. The recovered cyclohexanecarboxylic acid is freed from the solvent and recycled to the process. The acidic caprolactam solution containing excess sulfuric acid is then fed into the neutralization stage, where it is neutralized with ammonia. Neutralization is carried out directly in a crystallizer under reduced pressure. Two liquid layers are formed, a saturated ammonium sulfate solution and a concentrated aqueous caprolactam solution. The caprolactam solution is purified in several stages. It is first separated from the water-soluble byproducts by toluene extraction. An aqueous caprolactam solution is then obtained by countercurrent extraction of the caprolactam–toluene solution with water. The toluene-soluble byproducts remain in the organic layer. Water is removed from the aqueous caprolactam solution and the product distilled to give pure caprolactam.

Crystallization of the separated saturated ammonium sulfate solution gives 4.1 tons of ammonium sulfate per ton of caprolactam.

Research centered on reduction of ammonium sulfate production:

Cyclohexanecarboxylic acid is treated with oleum in the first version of this process to produce pentamethylene ketene.

The pentamethylene ketene is then nitrosodecarboxylated to caprolactam in the presence of oleum. Ammonium sulfate is decreased to 2 tons per ton of caprolactam by this route [61].

The second version produces no ammonium sulfate as a result of a modification in the separation procedure: Caprolactam dissolved in sulfuric acid is extracted by diluting the solution with small amounts of water, which is then extracted with an alkylphenol. The remaining sulfuric acid is subjected to thermal cracking, which destroys the impurities, and the SO_2 formed is recycled into the process. Aside from not generating ammonium sulfate, this version is also advantageous in that impurities do not present waste disposal problems [62].

4.4. Recovery from Nylon-6 Waste

Solid nylon-6 waste is depolymerized in a kettle operation with the aid of a cracking catalyst and superheated steam [63].

The mixture of steam and caprolactam leaving the kettle is fed to an evaporation column, where the mixture is condensed and concentrated under atmospheric pressure. The concentrate is purified by adding an oxidizing agent that converts impurities to readily removable compounds. The caprolactam is purified through distillation.

The washwater obtained from extraction of nylon-6 chips contains oligomers of caprolactam as well as caprolactam. The oligomers are separated after preconcentration in a thin-film evaporator and then depolymerized in the same manner as the solid waste. The resulting aqueous caprolactam solution is purified chemically. Subsequent distillation gives water, a fraction containing low-boiling compounds, and caprolactam as the principal product.

Oligomers can also be depolymerized by other methods [64], [65]. The washwater of nylon-6 chip production is concentrated at a sufficiently high temperature to maintain the oligomers in solution.

The caprolactam-oligomer solution is fed into a fixed- or fluidized-bed reactor. The oligomers are cracked at 275 – 350 °C.

A special aluminum oxide catalyst is used and a yield of 95 %, relative to the oligomers in the feed, is obtained. After cracking, the caprolactam is purified by conventional methods [65].

4.5. Former Commercial Routes

Union Carbide has developed a process for the manufacture of caprolactam based on the following reaction sequence [66]:

This reaction can be carried out by two methods:

Cyclohexanone is reacted with peracetic acid in an anhydrous medium, such as acetone. With an excess of cyclohexanone, ε-caprolactone is obtained in a yield of about 90 %.

Oxidation can also be carried out in situ. Cyclohexanone is reacted with air at 25 – 50 °C with the simultaneous introduction of acetaldehyde. An excess of cyclohexanone is also used in this case. Manganese, cobalt, platinum, palladium, vanadium, and zirconium salts and their oxides on carriers are examples of suitable oxidation catalysts. The acetic acid formed as a byproduct during the oxidation (about 1.1 kg per kg of lactam) is separated from the ε-caprolactone by distillation. The conversion of caprolactone to caprolactam with ammonia can either be carried out in anhydrous or aqueous medium, preferably at 350 – 425 °C at increased pressure. An excess of ammonia is used. The caprolactam formed during the ammonolysis of caprolactone in aqueous medium is isolated by extraction. The total yield is 65 – 70 %.

Union Carbide operated a plant with a capacity of about 20 000 t/a using this method.

Several companies have developed processes for the production of caprolactam using nitrocyclohexane as a starting product. Nitrocyclohexane is converted to cyclohexanone oxime by

partial reduction with hydrogen in the presence of silver oxide, zinc oxide, or chromium oxide catalysts in an aqueous phase [67], [68]. The yield can be increased by using lead-modified platinum and palladium catalysts [69]. The reduction is carried out under increased pressure at 100 – 150 °C. The byproducts include cyclohexylamine.

Du Pont operated a caprolactam plant based on catalytic reduction of nitrocyclohexane to cyclohexanone oxime with a capacity of about 25 000 t/a. Rearrangement was carried out in the conventional manner. The plant was shut down.

The catalytic conversion of nitrocyclohexane to caprolactam is a modified method never used industrially. The reaction is carried out over borophosphoric acid catalysts in the gas phase at 150 – 450 °C [70].

4.6. New Routes in Development

Several attempts are being made to develop new routes using cheaper raw materials or more economical reaction steps or minimizing byproducts and waste.

Hydrogen Peroxide Processes. Inventa describes a process for the production of cyclohexanone oxime by oxidation of cyclohexylamine with hydrogen peroxide in the presence of catalysts and stabilizers [71]. Salts of acids of group VI B metals are used as catalysts. The yield based on cyclohexylamine is 98 %. An adduct of 1 mol of cyclohexylamine and 1 mol of cyclohexanone oxime is formed as an intermediate, which is hydrolyzed to cyclohexylamine and cyclohexanone oxime.

Researchers of the former states of the USSR succeeded in catalytically converting cyclohexanone with hydrogen peroxide in the presence of ammonia in aqueous solution to cyclohexanone oxime [72]. Toa Gosei developed a process based on this approach [73]. The reaction is carried out with an excess of ammonia at 10 – 30 °C under atmospheric pressure. Tungsten and tin compounds are used as catalysts. The cyclohexanone oxime yield is said to be well above 90 %. The cyclohexanone oxime is obtained from the reaction mixture by extraction with organic solvents. About 95 % of the catalyst can be recovered from the aqueous solution. Catalyst still in solution is adsorbed on carbon.

Ammonium sulfate byproduct is formed by both the Inventa and Toa Gosei process during rearrangement of the cyclohexanone oxime.

Another hydrogen peroxide process known as the 1,1′-Peroxydicyclohexylamine Process has been demonstrated by BP Chemicals [74] and Degussa [75]:

Cyclohexanone is reacted with hydrogen peroxide in a molar ratio of 2 : 1 in the presence of an organic solvent, such as methanol, ethanol, or isopropanol, and a stabilizer, such as sodium ethylenediaminetetraacetate, to give 1,1′-dihydroxydicyclohexyl peroxide.

The peroxide reacts with ammonia to form 1,1′-peroxydicyclohexylamine. Salts of organic acids are used as accelerators. The reaction temperature for the first stage is 25 °C, while the second stage reacts at about 25 – 45 °C; the reaction can also be carried out in a single stage. 1,1′-Peroxydicyclohexylamine is converted to caprolactam and cyclohexanone in the presence of catalysts such as lithium halides; molten caprolactam is used as a solvent. The reaction mixture is then distilled at 100 – 115 °C and 1.3 – 2 kPa (13 – 20 mbar). Cyclohexanone is recycled and caprolactam is purified in a conventional manner.

This process proceeds without any byproduct formation.

Oxidation of Cyclohexylamine with Elemental Oxygen. Allied proposed the oxidation of cyclohexylamine to cyclohexanone oxime with elemental oxygen [76].

Cyclohexylamine vapor is brought into contact with oxygen. Helium is used as a diluent to keep cyclohexylamine and oxygen concentration outside the explosion limits. This gas is passed over silica gel catalyst at temperatures between 120 – 250 °C and adequate pressure. A yield of about 11 % per pass of the reaction mixture over the catalyst is reported.

The cyclohexanone oxime obtained can be processed to caprolactam in the usual way.

Direct Oximation of Cyclohexanone. Allied introduced a process for ammoximation of cyclohexanone [77].

Ammonia, air, and cyclohexanone react in the presence of silica, alumina, or gallia catalysts at temperatures between 50 and 500 °C. A solvent can be employed to remove cyclohexanone oxime from the catalyst.

A 40 % yield of cyclohexanone oxime is obtained.

Bis(nitrosocyclohexane) Process. Monsanto described a process for the production of cyclohexanone oxime using electrical discharge [78]. In this process, cyclohexane is reacted with either nitric oxide, alkyl nitrites, or nitroalkanes to form bis(nitrosocyclohexane). If the reaction is carried out at about 100 °C, the bis(nitrosocyclohexane) undergoes in situ rearrangement to give cyclohexanone oxime.

Pressure, temperature, ratio of reactants, residence time, and current density are important prerequisites for obtaining a good yield. Other companies have developed similar processes.

ε-Hydroxycaproic Acid – ε-Caprolactone Process. Caprolactam production via ε-hydroxycaproic acid and ε-caprolactone has long been known [79].

Teijin described a process for ε-hydroxycaproic acid production by oxidation of cyclohexanone with air in the presence of such catalysts as azoisobutyronitrile or cyclohexyl peroxide. Substantial amounts of adipic acid are formed as byproduct. The yield of ε-hydroxycaproic acid and adipic acid is about 80 % [80].

Several companies have attempted to produce caprolactam from ε-hydroxycaproic acid. ε-Hydroxycaproic acid and its esters, including ε-caprolactone, can be converted, either in the liquid or in the gas phase, to caprolactam using ammonia.

Suitable solvents for carrying out the reaction in the liquid phase are water, alcohols, chloroform, or dioxane. Nickel, cobalt [81], copper, palladium, platinum [82], etc. are suitable catalysts. The reaction is carried out between 140 and 475 °C and usually under pressure. The yield of caprolactam after three cycles is 96 – 98 % [83].

In the gas-phase process, ε-caprolactone or the esters of ε-hydroxycaproic acid together with hydrogen, ammonia and water are passed over catalysts at temperatures of about 120 – 320 °C. The catalysts are titanium dioxide, alumina, or silica and copper or nickel [84], or copper oxide/chromium oxide [85]. The caprolactam yield is 90 % or higher.

The production of ε-caprolactone from hexane-1,6-diol, and its conversion to caprolactam, has also been described [86].

2-Nitrocyclohexanone Process. Another process forming no byproducts has been proposed by Techni-Chem [17], [87].

Cyclohexanone is reacted with excess acetic anhydride in the presence of ketene at 140 °C to give cyclohexenyl acetate. The catalysts are sulfuric or hydroiodic acid. The amount of ketene is such that the acetic acid formed during acetylation of cyclohexanone with acetic anhydride is reconverted to acetic anhydride with ketene. The reaction mixture is removed from the residue by flash distillation under reduced pressure.

Unreacted cyclohexanone and acetic anhydride are separated and recycled. Cyclohexenyl acetate is converted to 2-nitrocyclohexanone in an exothermic reaction at 30 – 50 °C in excess acetic anhydride and concentrated nitric acid (acetyl nitrate). Excess acetyl nitrate is removed under reduced pressure, absorbed by acetic anhydride, and recycled to the nitration stage. 2-Nitrocyclohexanone, acetic anhydride, and the resulting acetic acid are separated. Acetic acid is recycled into the ketene generator and acetic anhydride is returned to the nitration stage.

2-Nitrocyclohexanone is then quantitatively cracked with excess aqueous ammonia at 40 – 60 °C to give the ammonium salt of ε-nitrocaproic acid. The aqueous solution of the ammonium nitrocaproate is hydrogenated in the presence of a Raney nickel catalyst at 100 °C and 2 MPa (20 bar). The conversion to ε-aminocaproic acid is virtually quantitative. After the removal of catalyst and ammonia, the 5 – 25 % aqueous ε-aminocaproic acid solution is converted to caprolactam at 300 °C and 10 MPa (100 bar). Caprolactam is then extracted from unreacted ε-aminocaproic acid. ε-Aminocaproic acid is returned to the cyclization

process. The process is illustrated by the following equation:

Teijin described a process for the manufacture of caprolactam from 2-nitrocyclohexanone. In this process, ring cleavage, hydrogenation, and cyclization are carried out in one step: 2-Nitrocyclohexanone is reacted with hydrogen in the presence of water and ammonia at 150 – 300 °C over hydrogenation catalysts [88].

3,3-Pentamethyleneoxaziridine Process. Leuna-Werke developed a process for the production of caprolactam by heating 3,3-pentamethyleneoxaziridine (cyclohexanone isoxime) [89].

This cyclohexanone isoxime is obtained by reacting excess cyclohexanone in aqueous ammonia solution in the presence of a water-immiscible organic solvent, with hypochlorite solution at − 10 to + 50 °C.

The cyclohexanone isoxime solution is then heated to 250 – 350 °C in an organic solvent. The distillate contains caprolactam. The conversion of 3,3-pentamethyleneoxaziridine to caprolactam can also be carried out in sulfuric acid.

Catalytic Deacetylation of *N*-Acetylcaprolactam. Kanebo discussed the preparation of caprolactam by treating *O*-acetylcyclohexanone oxime in steam over silica – alumina, silica – magnesia, or silica – zirconia catalysts. The reaction is carried out at 150 – 450 °C and reduced pressure [90].

N-Acetylcaprolactam is converted to caprolactam by reaction with cyclohexanone oxime in the presence of a catalyst. Caprolactam and *O*-acetylcyclohexanone oxime are separated by distillation.

O-Acetylcyclohexanone oxime is recycled to rearrangement [91].

Acetylene, Ethylene, Propylene, Butadiene, or Furfural based Processes. Figure 8 summarizes potential routes for the production of caprolactam.

However, none of these processes is used commercially.

4.7. Environmental Protection

Atmospheric and liquid wastes from caprolactam production require disposal methods that take local and legal restrictions into consideration:

1) Crude caprolactam extraction produces a vent gas stream containing traces of organic solvent which must be reduced to acceptable levels by physical methods such as carbon adsorption.
2) In all processes using Beckmann rearrrangement heavy bottoms in crude caprolactam extraction containing ammonium sulfate and other sulfur compounds are formed. They can be incinerated to produce sulfuric acid.
3) The residue of finished caprolactam distillation can be incinerated.

5. Quality Specifications

Industrial caprolactam is 99.9 – 99.94 % pure. Main contaminant is usually water amounting to 0.04 – 0.1 %.

High purity is requested by the users who operate processes sensitive to quality fluctuations.

Standard specifications for polymerization and subsequent processing to fibers and plastics are listed in Table 2

Table 2. Standard specifications of caprolactam (BASF)

Solidification point	min. 69 °C
Moisture content	max. 0.05 %
Permanganate absorption number	max. 5
Volatile bases	max. 0.5 meq/kg
Content of free bases	max. 0.1 meq/kg
Content of free acids	max. 0.05 mg/kg
Oxime content	max. 5 ppm
Color number of 50 % aqueous solution	max. 5 APHA
Absorbance 290 nm (50 % aqueous solution; cuvette length: 1 cm)	max. 0.05

Aqueous solutions of caprolactam should be clear in all concentration ranges

Figure 8. Routes for caprolactam production from furfural, acetylene, propylene, ethylene, and butadiene

The most important quality criteria are the ppm amounts of impurities which can be oxidized with potassium permanganate, as well as the basic impurities which are present in free or volatile form.

Quality specifications and the methods used for determining these values vary from manufacturer to manufacturer.

6. Analysis

Appearance and Solubility. Caprolactam melt is clear. A clear solution is obtained by dilution with water in all concentrations.

Permanganate Numbers. Two different approaches are used.

1) Visual comparison with standard solution: 1 mL of 0.01 N potassium permanganate solution is added to 100 mL of aqueous caprolactam solution at 20 °C. 0.01 N is equivalent to $c(1/5\,KMnO_4) \triangleq 0.01$ mol/L. The time taken for the color to change to that of the standard solution is measured. Typical values are shown in Table 3.
2) Photometric method: The absorbance of a 1 wt % caprolactam solution (50 mL or 100 mL aqueous solution) is measured 250 or 600 s after the addition of 0.01 N potassium permanganate (1 mL or 2 mL) at a specific wavelength and compared to water treated with permanganate.

Table 3. Permanganate numbers of caprolactam

Method	Concentration of the caprolactam/water solution	Standard solution composition in 1 L of water	Permanganate number in s
1	1 wt %	2.5 g $Co(NO_3)_2 \cdot 6H_2O$ + 0.01 g $K_2Cr_2O_7$	10000 to 40000
2	1 wt %	3 g $CoCl_2 \cdot 6H_2O$ + 2 g $CuSO_4 \cdot 5H_2O$	3600 to 4000
3	3 wt %	3 g $Co(NO_3)_2 \cdot 6H_2O$ + 0.012 g $K_2Cr_2O_7$	5000 to 10000

The extinction times 100 is referred to as the Klett-Summerson value or permanganate absorption number (Table 4).

Table 4. Permanganate absorption number of caprolactam

Method	Wave-length	Time, s	Extinction × 100
1	410 nm	250	Klett-Summerson value: max. 7
2	420 nm	600	permanganate absorption number: max. 5

Permanganate numbers can be converted into permanganate absorption numbers. A permanganate number of 10000 s (method 3/ Table 3) corresponds to a permanganate absorption number of 4 (method 2/Table 4).

Volatile Bases. Volatile bases are separated by steam distillation in the presence of aqueous sodium hydroxide, collected in a receiver, and determined by titration.

Methods differ in the caprolactam concentrations and the amounts of sodium hydroxide solution used. The amounts of volatile bases are expressed either in meq/kg or in mg of NH_3/kg.

Color Number. The color number is expressed in APHA units, and corresponds to the platinum – cobalt number, also referred to as Hazen color number or degree. It is used to determine the absorbance or extinction of a 50 wt % aqueous caprolactam solution. It is measured in comparison to standard solution or by photometric determination of the extinction compared to distilled water. The latter measurement is carried out in a 5-cm cell at wavelengths of 390 and 465 nm. The standard value amounts to 5 – 10 APHA units.

Solidification Point. The solidification point is determined by melt analysis. This analysis is related to the moisture content of caprolactam. The standard value amounts to 68.8 – 69.0 °C (corrected), corresponding to a moisture content of 0.04 – 0.1 % water.

The moisture content itself is determined by titration with Karl-Fischer solution.

Free Bases or Acids. The free base or acid content is measured by acidimetric titration to pH 7.0 of an aqueous caprolactam solution.

Residual Cyclohexanone Oxime. Cyclohexanone oxime is measured colorimetrically after hydrolysis to hydroxylamine, oxidation, diazotization, and formation of a colored diazonium compound or other methods.

Absorbance at 290 nm. The absorbance of a 50 % aqueous solution of caprolactam is measured at a wavelength of 290 nm and corrected to a cuvette length of 1 cm.

The International Organisation for Standardization (ISO) is attempting to standardize analytical methods for caprolactam. Methods for "Determination of crystallizing point – ISO 7060-1982", "Determination of colour of 50 % aqueous caprolactam solution – ISO DIS 8112-1983", and "Determination of absorbance at a wavelength of 290 nm – ISO 7059-1982" have been finalized and recommended.

7. Storage and Transportation

Molten caprolactam is stored and shipped in stainless steel or aluminum containers at 75 – 80 °C in the absence of moisture and under a blanket of nitrogen containing less than 10 ppm of oxygen.

Flaked caprolactam is supplied in polyethylene bags for general purposes or in aluminum coated paper bags for anionic polymerization. Flake caprolactam should be stored in dry warehouses and protected against direct sunlight. It is advisable to keep the ambient temperature below 45 °C (wherever possible) and the relative humidity below 65 %. In areas with high temperatures and humidity, an additional outer reinforced paper bag can be used for protection.

8. Economic Aspects

The United States, Japan, the Soviet Union, Belgium, the Netherlands, Italy, and Germany are the main producers of caprolactam. With the exception of France and the United Kingdom virtually all industrialized nations possess caprolactam facilities of their own.

World capacity is summarized in Table 5.

Table 5. Caprolactam capacities (kt/a) [8]

	1984	1989	1991	1994
Western Europe	845	775	841	843
FRG	–	120	160	180
USA	505	595	582	685
Latin America	115	–	–	–
Asia	615	–	–	–
Japan	(455)	469	531	519
Eastern Europe	800	–	–	–
World caprolactam capacity	2880	1959	2114	2227

Some 90 % of all caprolactam produced is processed to filament and fiber. Nearly 10 % is used for the production of plastics. Only small quantities are used for chemical syntheses.

9. Toxicology

Caprolactam is of relatively low acute toxicity: LD_{50} 1155 mg/kg (rat, oral) [92] resp. 1660 mg/kg (rat, oral); the symptoms of acute intoxication are tonoclonic convulsions. Rabbits and cats are more sensitive to caprolactam than rats [93].

Repeated epicutaneous application (50 % ether solution; 10 times) and intracutaneous injection (0.1 % in physiological NaCl solution) did not cause local irritation or sensitization to the skin of guinea pigs [93]. Other animal experiments, however, indicated weak sensitization [94]. Repeated instillation of 3 – 4 drops of a 5 % or 10 % solution into the conjunctival sac of the rabbit eye caused no irritation [95].

At the workplace caprolactam is usually inhaled as a vapor or dust. Repeated inhalations (7 times, 7 h) of dust containing 118 – 261 mg/m^3 was tolerated by guinea pigs without any symptoms except for occasional coughing [96]. In a subchronic inhalation study rats were exposed to relatively high concentrations of caprolactam (vapor: 500 mg/m^3; aerosol: 120 – 150 mg/m^3) 45 times for 4 h per day: the genital cycle of female rats was prolonged, the formation of follicles was retarded, and the reproduction of corpus luteum was stimulated [97].

Caprolactam was not teratogenic after oral administration of 1/10 of the LD_{50} (116 mg/kg) to rats from day 6 to 15 of gestation [98].

Effects on kidneys after chronic exposure are being discussed as the most important toxic effect [99].

Short-term screening for mutagenic/carcinogenic potential on bacterial and mammalian cells (Ames test, CHO test, cell transformation test) was negative for caprolactam [100].

When caprolactam was administered in the feed to mice (7500 and 15000 ppm) and rats (3750 ppm) over a period of two years no carcinogenic effect was observed; only the body weight gain was retarded with increasing concentrations [101].

Long-term experience in the handling of caprolactam has demonstrated that skin and eye irritation may occur. Skin sensitization is apparently very rare [102]. Long-term exposure of female workers to caprolactam (concentration: "a multiple of 10 mg/m^3") led to irregularities of menstruation and disorders during the course of pregnancy [97]. Another publication, however, reports no adverse health effects at workplace concentrations of 40 – 60 mg/m^3 [103].

Exposure levels are established at 1 mg/m^3 (TLV for dust) and 20 mg/m^3 (5 ppm; TLV for vapor) in the United States and at 25 mg/m^3 (MAK) in the Federal Republic of Germany.

1. Introduction

Carbamic acid, H_2NCOOH, the half amide of carbonic acid, does not exist as the free acid but forms numerous stable metal salts, esters, halides, amides (i.e., urea and urea derivatives), and simple or mixed anhydrides. A large number of derivatives result from replacement of the hydrogen atoms on the nitrogen atom by organic radicals.

2. Salts of Carbamic Acid

The salts of carbamic acid (carbamates) are relatively unstable. In aqueous solution they hydrolyze slowly at room temperature, and more rapidly on heating, to the corresponding metal carbonates and ammonia. Heating of the anhydrous solid produces cyanates from alkali-metal carbamates, and cyanamide from alkaline earth-metal carbamates.

Of the unsubstituted salts only *ammonium carbamate* (→ Ammonium Compounds, Chap. 4.2.) is made industrially. It is present in technical-grade ammonium carbonate (hartshorn, sal volatile) and is an intermediate, which is not isolated, in the industrial synthesis of urea.

3. Esters of Carbamic Acids

Carbamic acid esters are referred to as carbamates, in the same way as the metal salts, or by the trivial name urethane.

Physical Properties. The unsubstituted and the *N*-phenyl carbamates are generally crystalline, whereas the simple mono and di *N*-alkyl substituted compounds are liquids at ambient temperature. The physical data of the simple esters are shown in Table 1.

Preparation. There is no outstanding synthetic route to the esters. Depending on the carbamate to be prepared and the availability of the starting materials, one of the following methods has an economic advantage.

During the preparation of *N*-monosubstituted esters temperatures of 60 – 80 °C should not be exceeded, in order to prevent decomposition into isocyanate and alcohol.

Alcoholysis of Carbamoyl Chlorides:

$$R^1R^2N-COCl + R^3OH \xrightarrow{-HCl} R^1R^2N-COOR^3$$

In order to obtain good yields the reaction should be carried out in the presence of a base,such as a tertiary amine or pyridine, or in the presence of an acylation catalyst, such as 4-dimethylaminopyridine [5].

Aminolysis of Chloroformates:

$$2\,R^1R^2NH + ClCOOR^3 \longrightarrow R^1R^2N-COOR^3 + R^1R^2NH{\cdot}HCl$$

Since the second mole of amine neutralizers the hydrogen chloride no other base is required; however, acylation catalysts may be used if necessary. The reaction can also be carried out with tertiary amines with the formation of an alkyl chloride [6].

Reaction of Urea or Urea Nitrate with Alcohols in the Presence of Heavy Metals [7]:

$$H_2N-CO-NH_2 + ROH \xrightarrow{ZnCl_2} H_2N-COOR + NH_3$$

All the lower unsubstituted carbamates (e.g., methyl or ethyl carbamate) are prepared by this method.

Reaction of Alcohols with Isocyanates:

$$R^1NCO + R^2OH \longrightarrow R^1NH-COOR^2$$

Alkyl or aryl isocyanates yield monosubstituted carbamates, whereas isocyanic acid, HNCO, yields unsubstituted esters [8]. For the substituted isocyanates the order of reactivity is *prim.* alkyl > *sec*-alkyl > *tert*-alkyl > phenyl. Lewis bases such as triethylamine and Lewis acids such as dibutyltin dilaurate [9] are useful catalysts.

Transamidation of Simple Carbamates with Higher Amines:

$$R^1NH_2 + H_2N-COOR \xrightarrow{Cat.} R^1NH-COOR + NH_3$$

Zinc acetate is commonly used as the catalyst [10].

Transesterification of Lower Alkyl Carbamates with Higher Alcohols:

$$R^1R^2N-COOR^3 + R^4OH \xrightarrow{Cat.} R^1R^2N-COOR^4 + R^3OH$$

Aluminum isopropylate is commonly used as the catalyst [11].

Aminolysis of Dialkyl Carbonates:

$$R^1O-COOR^1 + HNR^2R^3 \rightarrow R^2R^3N-COOR^1 + R^1OH$$

Rearrangements of ω-Alkoxyalkyl- and ω-Phenoxyalkylcarbamoyl Chlorides [12]:

$$R^1O(CH_2)_nN\begin{matrix}COCl\\R^2\end{matrix} \longrightarrow Cl(CH_2)_nN\begin{matrix}COOR^1\\R^2\end{matrix}$$

Oxidative Amination of Carbon Monoxide:

$$R^1NH_2 + CO + R^2OH + 1/2\,O_2 \xrightarrow{Cat.} R^1NH-COOR^2 + H_2O$$

Preferred catalysts are iron compounds [13] in the presence of small amounts of a noble metal.

Reductive Carbonylation of Organic Nitro Compounds:

$$C_6H_5NO_2 + CO + R^1OH \xrightarrow{Cat.} C_6H_5NH-COOR^1$$

The usual catalyst is palladium together with an iron compound [14].

Uses. Carbamates are used mainly as crop protection agents and pharmaceuticals, with the greater proportion being used as insecticides, herbicides, and fungicides. For examples, see page 4.

Of the simple carbamates, the methyl ester and the ethyl ester (urethane) still have a certain importance, especially as starting materials for the preparation of higher carbamates. The condensation product of ethyl carbamate and formaldehyde is used to give a crease-resistant finish to textiles [15].

4. Carbamoyl Chlorides

Carbamoyl chlorides, also known as carbamic acid chlorides, are industrially important as intermediates because of their ready availability and of their reactivity.

Physical Properties. The simple carbamoyl chlorides are colorless liquids or solids, usually with pungent odor. The physical properties of the most important carbamoyl chlorides are given in Table 2.

Chemical Properties. Carbamoyl chloride, $H_2N-COCl$, is unstable; it may be stabilized by Lewis acids (e.g., aluminum chloride) as adducts and in this form can be used in the Friedel-Crafts acylation of arenes [16]. Since many of the monosubstituted carbamoyl chlorides also deteriorate on storage, the corresponding isocyanates are used instead. Disubstituted carbamoyl chlorides are stable and can be stored for prolonged periods.

In their chemical behavior the carbamoyl chlorides resemble the carboxylic acid chlorides. Their most important reaction is the nucleophilic displacement of the chlorine atom.

Since carbamoyl chlorides are less reactive than carboxylic acid chlorides, acid acceptors or acylation catalysts such as 4-dimethylaminopyridine are generally used in reactions involving the liberation of hydrogen chloride. Table 3 gives an overview of the reactions of carbamoyl chlorides.

Hydrolysis of carbamoyl chlorides yields the corresponding substituted ammonium chloride and carbon dioxide instead of the unstable carbamic acid. This reaction is used to remove traces of carbamoyl chloride vapor from exhaust gases or to render residues harmless.

Production. In industry phosgene, $COCl_2$, is usually the starting material.

$$COCl_2 + R^1R^2NH \longrightarrow R^1R^2N-COCl + HCl$$

R^1, R^2 = alkyl, alkoxy, aryl

At low reaction temperatures (cold phosgenation) the hydrogen chloride liberated removes half the amine as the ammonium salt $R^1R^2NH \cdot HCl$. Complete conversion of valuable amines into the corresponding carbamoyl chlorides is achieved by adding a base, e.g., pyridine.

The same is achieved by the use of higher temperatures (about 90 – 100 °C, hot phosgenation) in which case the hydrogen chloride is removed from the reaction mixture as a gas. Crystallization of the substituted ammonium chloride during the course of the reaction can lead to difficulties with stirring or to blockage of the reactor. Sometimes, however, the amine salt is used as the starting material. Phosgenation is carried out at room temperature because the salt, unlike the free amine, does not react with the carbamoyl chloride already formed to produce a substituted urea:

$$R^1R^2NH + R^1R^2N-COCl \longrightarrow R^1R^2N-CO-NR^1R^2 + HCl$$

To repress urea formation, excess phosgene is used together with an appropriate amount of solvent as a diluent. Good mixing must also be employed to prevent any local excess of amine.

The solvent used should be a good solvent for phosgene, e.g., toluene, chlorobenzene, or ethyl acetate [19], and should be easily separable from the carbamoyl chloride, i.e., the boiling point difference must be great enough. This separation is not required when the carbamoyl chloride serves as the reaction medium [25].

Table 2. Physical properties of some carbamoyl chlorides

N-Substituents	Formula	M_r	CAS reg. no.	*mp*, °C	*bp*, °C	Density,
	$H_2N-COCl$	79.49	[*463-72-9*]	ca. 50	61–2

Phenyl	$C_6H_5NH-COCl$	155.58	[*2040-76-8*]	59		
Diphenyl	$(C_6H_5)_2N-COCl$	231.68	[*83-01-2*]	85	138 (0.13 kPa)	

The amine also reacts in the gas phase with phosgene, if necessary in a diluent inert gas (e.g., nitrogen), at temperatures above 250 °C [26]. Carbamic acid chloride can be prepared in this way from ammonia and phosgene at 400–450 °C [16].

Phosgene also reacts under mild conditions (50–60 °C) with tertiary amines containing at least one lower alkyl group (preferably methyl or ethyl) to give alkyl halides as byproducts [27]:

$$COCl_2 + R^1R^2NR^3 \longrightarrow R^1R^2N-COCl + R^3Cl$$

R^3 = methyl or ethyl

Carbamoyl chlorides can also be obtained by the addition reaction of phosgene to the C=N double bond of azomethines [28–30]. α-Chloro- or α,β-unsaturated carbamoyl chlorides are formed, depending on the reaction conditions:

In the laboratory, carbamoyl chlorides may be prepared by the addition of hydrogen chloride to isocyanates:

$$RNCO + HCl \longrightarrow RNH-COCl$$

or by the chlorination of disubstituted formamides with sulfur dichloride, SCl_2, sulfuryl chloride, SO_2Cl_2 [31], phosphorus trichloride, PCl_3, or thionyl chloride, $SOCl_2$ [32]:

$$R^1R^2N-CHO \longrightarrow R^1R^2N-COCl$$

or by the action of phosphorus oxychloride, $POCl_3$, or phosphorus pentachloride, PCl_5, on carbamic acid esters [33]:

$$R^1R^2N-COOR^3 \longrightarrow R^1R^2N-COCl$$

as well as by carbonylation of chloramines [34]:

$$R^1R^2N-Cl + CO \longrightarrow R^1R^2N-COCl$$

Table 3. Chemical reactions of carbamoyl chlorides [16–24]

 Disubstituted carbamoyl chloride with tertiary alkyl group	$\xrightarrow{Heat}$	$R^1NCO + R^2R^3R^4CCl$ Isocyanate

Uses. As is apparent from the reactions shown in Table 3, carbamoyl chlorides are intermediates with many uses. Of primary industrial importance are the reactions with alcohols, phenols, and oximes to give carbamic acid esters; with thiols (mercaptans) to give thiocarbamates; with amines and hydroxylamines to give substituted ureas; and with imidazoles and triazoles to give carbamoyl azoles. All these are important classes of compounds in crop protection (→ Fungicides, Agricultural; → Weed Control; → Insect Control). The following crop protection materials are examples of products derived from carbamoyl chlorides:

Carbofuran (insecticide)

Temik (insecticide)

Dimetilan (insecticide)

Eptam (herbicide)

Linuron (herbicide)

Sportak (fungicide)

Handling and Transportation. The industrially important lower carbamoyl chlorides in particular are chemically and biologically (see Chap. 5) active substances. The selection of suitable apparatus and corrosion resistant materials (e.g., glass, polytetrafluoroethylene, glass-lined steel, or, if necessary, tantalum or Hastelloy) requires much care and due attention must also be given to the various regulations existing in different countries. In the Federal Republic of Germany, for example, dimethylcarbamoyl chloride and *N*-chloroformylmorpholine (morpholinocarbamoyl chloride) are specifically mentioned in Appendix II No. 1 of the regulations dealing with dangerous materials [35] as well as in Appendix II of the regulations dealing with noxious emissions [36].

Most of the details about technical safety data are to be found in [37–39].

5. Toxicology and Occupational Health

Ethyl Carbamate. There is little data available on the acute effects of this compound: the median lethal dose (LD_{50}) upon oral administration in mice is 2500 mg/kg [40].

The most important toxicological effect is its *carcinogenicity.* Ethyl carbamate has proved to be carcinogenic in mice, rats, and hamsters upon oral, inhalative, subcutaneous, or intraperitoneal administration [41]. Lung tumors, lymphomas, hepatomas, melanomas, tumors of the blood vessels, and skin tumors (upon treatment of the skin) have occurred in the tests. The carcinogenic effects were observed upon administration of the following doses: lifelong treatment of rats with 1 ppm ethyl carbamate in drinking water; lifelong treatment of hamsters with 0.2 % ethyl carbamate in drinking water; two treatments (once a week) of the skin of mice with 120 mg ethyl carbamate, followed by eighteen applications (once a week) of 0.3 mL of a 0.5 % preparation in croton oil; inhalative treatment of mice (20 – 60 min per d) with aerosols containing varying amounts of ethyl carbamate, for a maximum of 14.5 weeks. Even short-term treatments, for example, a ten-day treatment of young mice with 0.4 % ethyl carbamate in drinking water, led to the development of tumors. Further investigations have confirmed the types of effects described here.

Ethyl carbamate has been classified by the MAK commission as being a carcinogen in animal experiments and is listed in group III A/2.

Diethylcarbamoyl Chloride. The median lethal dose (LD_{50}) upon oral administration to rats is about 200 mg/kg [42]. The compound is irritating to skin and eyes. The inhalation of an atmosphere saturated with its vapors at 20 °C is lethal to rats after 3 h [43]. Diethylcarbamoyl chloride has proved to be mutagenic on *E. coli* strains in mutagenicity tests [44]. It is weakly mutagenic in high doses in the Ames test [45]. In view of these results and on account of the structural similarity to dimethylcarbamoyl chloride, a carcinogenic potential cannot be ruled out. The MAK commission has listed this substance in group III B.

Dimethylcarbamoyl Chloride. The LD_{50} is 1170 mg/kg upon oral administration to rats and 350 mg/kg upon intraperitoneal administration to mice. The compound is irritating to the skin and eyes. All the test animals survived an 8-min inhalation test in an atmosphere saturated with

vapors of the substance at 20 °C. Longer exposure times led to death. No sensitization was observed in animal experiments [46].

Dimethylcarbamoyl chloride proved to be a mutagen in numerous short-term tests for mutagenicity. They included the Ames test [47], [48], cell transformation test [49], sister chromatid exchange [50], [52], and micronucleus test [51]. The compound caused damage to the DNA of bacteria, fungi, and plants, but not in mammalian cells in vitro. It was mutagenic in bacteria, fungi, and plants, as well as in mammalian cells in vitro; however, it was not mutagenic in insects. Chromosomal aberrations were observed in fungi and plants, and in mammalian cells in vitro and in vivo, but not in humans. A review is given in [53].

Dimethylcarbamoyl chloride is carcinogenic in animal experiments. Mice developed tumors at the site of application upon percutaneous treatment with 2 mg substance in 0.1 mL acetone, three times weekly, for 492 d. Its tumorigenic effect was confirmed in another dermal application study. The subcutaneous application of dimethylcarbamoyl chloride to mice (weekly injection of 5 mg substance in 0.05 mL tricapryline over a period of 26 weeks) also caused local tumors and – as with percutaneous treatment – reduced the survival rate. Intraperitoneal treatment of mice (weekly dose of 1 mg substance in 0.05 mL tricapryline over a period of 450 d) led to increased incidences of lung tumors [54]. Lifelong inhalation of 1 ppm of dimethylcarbamoyl chloride over 6 h every day led to squamous cell carcinomas of the nasal mucosa in 51 % of the hamsters employed. In a comparable study using more sensitive rats, 96 % of the animals developed tumors of the respiratory tract [55]. The MAK commission has listed this substance in group III A/2; in the LV list dimethylcarbamoyl chloride is in group A 2.

Diphenylcarbamoyl Chloride. The LD_{50} in rats after a single oral administration is above 2000 mg/kg. It is not irritating to the skin and eyes but caused sensitization in animal experiments [56].

Morpholinocarbamoyl Chloride. Its acute toxicity in rats is relatively small. The LD_{50} after oral administration of the substance in peanut oil is about 3500 mg/kg.

The compound is only weakly mutagenic in the Ames test. However, in view of the instability of the compound in aqueous solutions, it is doubtful whether it is only a weak mutagen.

Weekly subcutaneous injection of rats with 300 mg/kg in peanut oil over more than 140 d led to tumors around the site of injection after 140 d. This treatment caused the death of all the animals within 340 d. As many as 58 of the 60 test animals in the test developed fibrosarcomas at the site of injection, and two animals developed adenocarcinomas of the mamma. Weekly subcutaneous treatment with 100 mg/kg in peanut oil over 140 d led to the death of all the rats within 335 d. As many as 59 of the 60 animals showed a sarcoma at the site of injection; in contrast, there were only three incidences of tumors among the sixty control animals treated with peanut oil alone. Morpholinocarbamoyl chloride has been listed in group III A/2 by the MAK commission [57].

Carbazole (dibenzopyrrole) [*86-74-8*], $C_{12}H_9N$, was first found in coal tar by C. Graebe and C. Glaser in 1872.

1. Physical Properties

M_r 167.21; *mp* 246 °C, *bp* at 101.3 kPa 354.8 °C; $d_4^{18} = 1.1035$ g/cm^3; plates or tables; sublimable; readily soluble in acetone and pyridine, slightly soluble in diethyl ether and ethyl alcohol, barely soluble in chloroform, acetic acid, carbon tetrachloride, and carbon disulfide, soluble in concentrated sulfuric acid, almost insoluble in water (ca. 1 mg/L at 25 °C); heat of fusion 176.3 kJ/kg; heat of combustion 3.719×10^4 kJ/kg at 25 °C.

2. Chemical Properties

The N-hydrogen atom of carbazole which is a secondary amine can be substituted with alkali metals. During halogenation, nitration, and sulfonation, substitution initially takes place at the 3- and 6-positions; the 1,3,6- and 1,3,6,8-derivatives are formed under more rigorous conditions.

Hydrogenation yields 1,2,3,4-tetrahydro-, hexahydro-, or dodecahydrocarbazole. Oxidation with chromates gives 3,3′-dicarbazyl, with permanganate 9,9′-dicarbazyl. Carboxylation with alkali and carbon dioxide gives, depending on the temperature, carbazole-3- or carbazole-1-carboxylic acid. Alkylation yields *N*-alkylcarbazoles.

3. Production

High-temperature coal tar contains an average of 0.9 % carbazole. Carbazole is obtained as a co-product in the production of anthracene. Due to its higher boiling point and better solubility, it can be separated from anthracene by extraction or complexation [6] with pyridine, ketones, benzene/methanol, *N*-methylpyrrolidone, dimethylacetamide, dialkyl sulfoxides, or dialkylformamides, by azeotropic distillation with ethylene glycol, or by selective hydrogenation of the anthracene [7] (→ Anthracene). The chemical separation of carbazole by means of potassium hydroxide or concentrated sulfuric acid fusion has become uneconomical. Pyridine mother liquors obtained from the preparation of pure anthracene yield pure carbazole by means of concentration and recrystallization from chlorobenzene.

Carbazole can be synthesized by converting cyclohexanone azine to octahydrocarbazole and subsequent dehydrogenation [8], by reductive cyclization of 2-nitrobiphenyl [9, 10], or by dehydrogenation and cyclization of diphenylamine [11 – 14], *o*-aminobiphenyl [15 – 17], or

© 2006 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a05_059.pub2

N -cyclohexylideneaniline [18]. These synthetic processes are not yet of industrial significance, because sufficient quantities of carbazole can be prepared from coal tar. A modern method to produce carbazole from coal tar is solvent-free, high-temperature melt crystallization (→ Anthracene).

4. Analysis

Gas – liquid chromatography is suitable for the quantitative determination of carbazole in complex mixtures, such as in coal tar or coal-tar fractions [19]. Thin-layer chromatography can also be used to identify carbazole along with other compounds [20]. Purity is determined by UV spectroscopy. As little as 0.005 % carbazole in anthracene can be detected by phosphorescence spectroscopy. Small quantities of phenanthrene do not interfere with the results [21].

5. Uses and Economic Aspects

Carbazole is obtained from coal tar in amounts of more than 3500 t/a, primarily for dye synthesis.

The blue sulfur dye Hydron Blue [22] is commercially synthesized by condensing carbazole with *p*-nitrosophenol and subsequent sulfurization (→ Sulfur Dyes). Its 2-hydroxy-3-carboxylic acid amides (Naphtol AS-LB, -SG, -SR; → Azo Dyes), anthraquinone vat dyes from phthaloyl carbazoles (→ Anthraquinone Dyes and Intermediates), styryl dyes from *N*-ethylcarbazole (→ Methine Dyes and Pigments), dioxazine dyes and pigments from *N* -ethyl-3-aminocarbazole (→ Azine Dyes ; → Pigments, Organic), and reactive dyes [23] can also be synthesized from carbazole.

The insecticide Nirosan, 1,3,6,8-tetranitrocarbazole, has been commercially available since 1939. *N* -Vinylcarbazole is polymerized to give poly(vinylcarbazole) (Luvican, Polectron) [24], which is thermally and chemically stable and has a high softening temperature and low dielectric loss and photoconductivity. These properties make it useful in electrical industry and for electrostatic copying methods [24 – 28]. Methacrylate carbazole polymers can be used as photorefractive materials. These materials combine photoconductivity and electro-optic properties. Applications are high-density optical data storage, optical image processing, dynamic holography, and optical computing [29, 30]. Carbazole compounds can also be used as host materials for triplet emitters in light-emitting diodes [31, 32]. Carbazole reacts with phenols and formaldehyde in the presence of acidic catalysts to give novolaks. These can be cured with hexamethylenetetramine to form highly heat – resistant polymers [33]. Concrete plasticizers are obtained by co-condensation of carbazole with phenols and formaldehyde and subsequent sulfonation [34]. Thermal condensation of 3,6-diaminocarbazole with dicarboxylic acid gives elastic and thermally stable polyamides [35].

6. Derivatives

N-Ethylcarbazole [*86-28-2*], $C_{14}H_{13}N$; M_r 195.27; *mp* 68 °C; by ethylation of carbazole – potassium with diethyl sulfate [36].

1,3,6,8-Tetranitrocarbazole [*4543-33-3*], $C_{12}H_5O_8N_5$; M_r 347.20; *mp* 312 °C; by nitration of carbazole with a mixture of nitric and sulfuric acid.

N-Vinylcarbazole [*1484-13-5*], $C_{14}H_{11}N$; M_r 193.25; *mp* 65 °C; from carbazole – potassium with ethylene oxide or vinyl chloride, or from carbazole and acetylene [24].

7. Toxicology and Environmental Aspects

Toxicology. The LD_{50} of carbazole ranges from 200 mg/kg (intraperitoneal, mice) to more than 5000 mg/kg (oral, rats) [37, 38]. Hence, it can be considered as nontoxic. Folliculitis and comedos were reported by workers with carbazole contact [39]. In animal studies, no skin- and eye-irritating potential was observed [40, 41], even under photoactivating conditions [42]. In rats and rabbits, carbazole is glucuronized and excreted in the urine [43]. There is some evidence for carbazole inducing carcinomas in the liver and forestomach of $B6C3F_1$ mice fed high doses of ca. 270 – 1050 mg (kg bw)$^{-1}$ d^{-1} for 96 weeks [44, 45], whereas no tumorigenic activity was noted in the liver and lung of newborn-mice following threefold intraperitoneal injection of carbazole [46]. Carbazole is not classifiable as to its carcinogenicity to humans (Group 3) [47]. Carbazole was not mutagenic in numerous bacterial assays [48 – 52]. No abnormalities in the intrauterine development of rats was observed following dermal administration of up to 250 mg (kg bw)$^{-1}$ from day 0 to 20 of gestation [52].

9-Ethylcarbazole produced a weak increase in the mutation rate in the bacterial tester strain *Salmonella typh.* TA100 after metabolic activation [49], but was inactive in a different complete Ames test [50].

Environmental Fate and Toxicity. Carbazole is biodegradable by adapted microorganisms in water [53, 54] and soil [55], but elimination of the dissolved organic carbon (DOC) to more than 90 % (according to OECD guideline 301E) is compatible with ready biodegradability [56]. In a model ecosystem including degradation and distribution processes, >99.5 % of initial carbazole disappeared from the water phase within 33 d, resulting in a spectrum of unidentified polar and nonpolar conversion products. N-methylation, N-acetylation, and presumably ring oxidation were relevant metabolic pathways in the test organisms (alga, snail, fish, and mosquito) which accumulated part of carbazole [57].

Photodegradation of carbazole in water is rapid; the elimination half-life was measured to be 2.9 h under simulated sunlight conditions [58].

The moderate water-partition coefficient (log P_{ow} = 2.58, 3.34 – 3.84 [56, 57, 59, 60]) indicates a significant bioconcentration potential.

However, bioconcentration factors (BCF) were found to be relatively low at ca. 125 and 500 in fish [57, 61] and about 110 and 115 in daphnia [62, 63].

Based on the molecular structure and photochemical properties, carbazole is predicted to be nonphototoxic to fish [64]. Exposure of daphnia to 0.11 mg/L for 48 h combined with 24-h continuous UV irradiation failed to produce mortality [62].

Acute aquatic toxicity was observed in fish and daphnia above water solubility: An approximate 48-h LC_{50} of about 1 mg/L is reported for saltwater fish (striped mullet) [65], and a 96-h LC_{50} for freshwater fish (zebra fish) of 4.31 mg/L [56]. In daphnia, the EC_{50} was >100 mg/L [56].

For the protozoa *Tetrahymena pyriformis*, the EC_{50} (72-h) was found to be nominally 20 mg/L [66].

High aquatic toxicity in the range of water solubility was found in algae (*Scenedesmus subspicatus*) with a mean inhibitory concentration IC_{50} (96-h) of 0.214 mg/L [56]. However, in another test using the alga *Scenedesmus acuminatus*, no toxic effect was noted up to 10 mg/L [67].

1. Survey

Most of the elements form binary compounds with carbon, all of which can be called carbides. The properties of these carbides are very different; therefore, like binary hydrides and nitrides, the carbides should be classified into groups. To avoid too many subdivisions, the following four types of carbides may be defined:

1) saltlike carbides of metallic elements, e.g., CaC_2
2) metal-like carbides of metallic elements, e.g., WC
3) diamond-like carbides, e.g., B_4C
4) carbides of nonmetallic elements, e.g., CO

This classification suggests another group: the elements that do not react with carbon, e.g., Sn.

Generally, the four groups of carbides can not be strictly separated from each other. Numerous carbides are in intermediate positions between these groups. One example is BeC_2 [*57788-94-0*]. It is a typical saltlike carbide and is decomposed by water. On the other hand, it may be viewed as a diamond-like carbide because of its hardness and other properties resembling those of SiC.

Figure 1 surveys the four types of carbides in the form of a periodic table. Elements that do not form binary compounds with carbon, or are not known to form carbides, are not shown. The carbides of the iron group and manganese are a subgroup of the metal-like carbides.

1.1. Saltlike Carbides

Saltlike carbides of metallic elements are the carbides of the elements of groups 1 – 3 and 11 – 13 (I – III, both A's and B's) of the periodic table, the lanthanides and actinides included. Exceptions are Ga, In, and Tl, which do not form carbides, and B_4C, which is a typical diamond-like carbide.

The saltlike carbides – also called ionic carbides – are attacked by water to form hydrocarbons. Most of these carbides form acetylene, e.g.:

$$CaC_2 + 2\,H_2O \longrightarrow Ca(OH)_2 + C_2H_2$$

These carbides can be viewed as salts of acetylene and may be called acetylides. The crystals contain C_2^{2-} anions.

10.1002/14356007.a05_061

Figure 1. Survey of binary compounds of carbon with the elements

The carbides Be_2C and Al_4C_3 form pure methane when hydrolyzed:

$$Be_2C + 4\,H_2O \longrightarrow 2\,Be(OH)_2 + CH_4$$

$$Al_4C_3 + 12\,H_2O \longrightarrow 4\,Al(OH)_3 + 3\,CH_4$$

In the crystal lattice of these carbides, the carbon atoms are isolated from each other, in contrast to the C_2 groups of the acetylides. The Be_2C lattice is antiisotypical to that of CaF_2.

The carbide MgC_2 can be decomposed by heating to form Mg_2C_3 and graphite. Hydrolysis of Mg_2C_3 yields propyne:

$$Mg_2C_3 + 4\,H_2O \longrightarrow 2\,Mg(OH)_2 + CH_3{-}C{\equiv}CH$$

In their carbides the lanthanides and actinides are mainly divalent. During hydrolysis they become trivalent, and hydrogen is formed in this reaction:

$$M^{2+} + H^+ \longrightarrow M^{3+} + H$$

This hydrogen reacts with the acetylene also formed to produce a mixture of acetylene, methane, ethylene, and hydrogen.

Whereas the saltlike carbides of groups 1 and 2 are transparent and are not electrical conductors, the lanthanide and actinide carbides show some metallic behavior, an indication of a state intermediate between saltlike and metal-like carbides. The electrical conductivity and metallic luster may be due to the fact that the metals are divalent in their carbides and the third valence electron is available for metallic bonding.

One other subgroup of saltlike carbides should be mentioned: the alkali-metal – graphite compounds. They are formed by absorption of molten Na, K, Rb, and Cs by graphite. Compositions such as MC_8, MC_{16}, and MC_{60} are known. These compounds are quite likely not chemical compounds, but merely adsorptional compounds, and perhaps better not called carbides.

1.2. Metal-like Carbides

Metal-like carbides of metallic elements are the carbides of the transition elements of groups 4, 5, and 6 of the periodic table. These carbides, also called metallic carbides, are not attacked by water. The metallic character of these compounds is shown in their high thermal and electrical conductivity as well as in their metallic luster.

All the metallic carbides are stable at room temperature and resist attack by dilute acids as well as by alkaline and organic liquids. Their hardness and wear resistance are utilized in the cemented carbides (→ Hard Materials), which are sintered products of the carbides with cobalt or other metals. Because of their industrial significance, these carbides are described in more detail in Chapter 2.

The carbides of Mn, Fe, Co, and Ni are generally included in the metal-like carbides, although they are really better classified as a group on their own. These carbides are in an intermediate position between the metal-like carbides and the saltlike carbides. Their crystal structures are quite different from the structures of the metal-like carbides and the saltlike carbides. The pure compounds are attacked by water or dilute acids.

1.3. Diamond-like Carbides

Diamond-like carbides include, strictly speaking, only B_4C and SiC. They are called diamond-like because of their extreme hardness, which is exceeded only by diamond itself. Sometimes the very hard Be_2C is included in the diamond-like carbides. However, its hardness cannot be used industrially, because of its decomposition by water.

1.4. Carbides of Nonmetallic Elements

Such carbides as CO, CS_2, and CCl_4, the carbides of nonmetallic elements, have covalent, molecular character and are not discussed in this article.

1.5. Crystal Structure

The lattice structure of most carbides can be deduced from the structure of their most important group, the metal-like transition-metal carbides. Basically these carbides are cubic or hexagonal closest packings of metal atoms with the smaller carbon atoms in the interstitial sites. Therefore,

the transition-metal carbides can also be called interstitial carbides.

In 1931 HÄGG [7] reported that the structure of the transition-metal carbides is determined by the radius ratio r of the metal and carbon atoms $r = r_C/r_{metal}$. When r is less than 0.59, the metals form the simple structures just described, with the carbon atoms located at the octahedral interstices. If all interstices are occupied in a body-centered cubic (bcc) metal lattice, the result is the face-centered cubic (fcc) sodium chloride structure. All the carbides of transition-metal groups 4 and 5 crystallize in this B1 lattice. Tungsten carbide has a simple hexagonal structure with all of the trigonal prismatic interstitial sites occupied by carbon.

The B1 carbides, principally TiC, ZrC, HfC, and VC, tend to form defect structures in which the interstitial sites are not completely filled. Broad homogeneity ranges are the result, but some substructures with overlapping homogeneity ranges are indicated [8].

When only one-half of the octahedral interstitial sites are occupied in an hexagonal-closest-packed (hcp) metal structure, the subcarbides – V_2C, Nb_2C, Ta_2C, Mo_2C, and W_2C – are obtained. This is a simplified interpretation, and in fact the subcarbides are more complex structures, as was shown by NOWOTNY [9]. Indeed, these structures are sometimes called Nowotny phases, to contrast them with the simpler Hägg phases.

When Hägg's ratio exceeds 0.59, the simple phases can no longer be formed as before. Close to 0.59 and in the case of low carbon content, there are the compounds $Cr_{23}C_6$ and $Mn_{23}C_6$, which can still be viewed as interstitial structures. For higher values of r and higher carbon content, more complex structures, no longer interstitial compounds, are formed: M_3C, M_7C_3, M_3C_2. These stoichiometries are primarily found in the iron group. These more complex structures are less metallic than the Hägg phases. Hardness, melting point, and chemical resistance are markedly lower.

The structures of the saltlike carbides can also be deduced from the Hägg phases. When there are more carbon atoms than octahedral interstitial sites in the metal lattice, pairs of carbon atoms are formed. The CaC_2 type is a tetragonally deformed B1 structure. The dicarbides of the lanthanides and actinides crystallize in this system. They lack metallic characteristics. The bcc carbides, M_2C_3, also contain C_2 groups, e.g., U_2C_3.

The structures of the diamond-like carbides SiC and B_4C differ from all structures described thus far. The carbide SiC has an expanded diamond lattice, whereas B_4C crystallizes in a rhombic lattice containing B_{12} icosahedrons and C_3 chains.

1.6. General Production Processes

There are a number of general methods of producing carbides:

1) Nearly all carbides can be prepared at high temperature by direct reaction from the metal powder mixed with lamp black or graphite, e.g.:

   $$W + C \longrightarrow WC$$

   Generally the temperature is in the range 1000 – 1500 °C, and special furnaces are used. A protective atmosphere or vacuum is needed.
2) Instead of the pure metal, the oxide or hydride can be carburized with solid carbon:

   $$Ta_2O_5 + 7\,C \longrightarrow 2\,TaC + 5\,CO$$

   Large amounts of gas result from this reaction. Both processes 1 and 2 are solid-state reactions.
3) Carbides with high melting points can be prepared by a modified aluminothermic process:

   $$3\,Cr_2O_3 + 6\,Al + 4\,C \longrightarrow 2\,Cr_3C_2 + 3\,Al_2O_3$$
4) Instead of solid carbon, gaseous carbon compounds, such as CO or CH_4, can be used. This process is important in the steel industry, where mainly iron, chromium, and manganese carbides are formed during fusion:

   $$3\,Fe + 2\,CO \longrightarrow Fe_3C + CO_2$$
5) Reaction of metal chlorides with hydrocarbons in a hydrogen atmosphere produces carbides:

   $$ZrCl_4 + CH_4 \longrightarrow ZrC + 4\,HCl$$

   This method is used to produce layers of carbides on other materials by chemical vapor deposition (CVD → Thin Films).

Most of the saltlike carbides are prepared by processes 1 and 2, by heating the metals or oxides with carbon, e.g.:

$$CaO + 3\,C \longrightarrow CaC_2 + CO$$

However, another, quite different process can also be used:

Reaction of acetylene with metals or salts dissolved in water or liquid ammonia or suspended in inert organic fluids forms simple or complex acetylides. Most are metastable but are stabilized by H_2O, NH_3, or acetylene itself. Cautious decomposition produces individual carbides:

$$Li\,(s) + NH_3\,(l) + C_2H_2 \longrightarrow LiHC_2 \cdot NH_3 + 0.5\,H_2$$

$$LiHC_2 \cdot NH_3 \longrightarrow LiHC_2 \longrightarrow Li_2C_2$$

Today this last method is primarily of laboratory interest.

1.7. Uses

The uses of carbides are as diverse as the types of carbides. Most important from an economic point of view are the carbides of the transition metals of groups 4, 5, and 6. The most important of these is tungsten carbide. The hardness and chemical resistance of these carbides are the basis for their use by the tool and machine industry in multitudinous applications as *cemented carbides.* The terms *hardmetals* and cemented carbides are synonymous. The term *cermet* is also used for some or all of these composites. Furthermore the term *tungsten carbide* is used because WC is the main constituent in most of these materials. These cemented carbides are sintered products of one or more carbides with a metallic binder, preferably the metal cobalt. There are many different combinations of carbides and binder metals. Factories producing cemented carbides are found in every industrial country; the world's annual production is estimated at ca. 20 000 t in 1985. Some tungsten carbide combined with Cu or Ag is used in electrical contacts and in fuel cells.

The carbides of manganese and iron are never used alone like the harder transition-metal carbides, but rather are formed in alloys during fusion. These carbides, especially cementite, Fe_3C, are of fundamental importance because the individual carbides and the binary mixed carbides with V, Cr, Mo, and W are responsible for the hardness of steel, Stellites, and related alloys.

The most important saltlike carbide is CaC_2 (→ Calcium Carbide). One-half of the world's annual production, several million tons, is converted to cyanamide (→ Cyanamide), which is used as fertilizer. Some 20 % is used for acetylene production (→ Acetylene, Chap. 4.3.4.), and the remainder is used in steelmaking as a carburizing additive (→ Steel).

The monocarbides and dicarbides of uranium and thorium are used as nuclear fuels in high-temperature reactors. These carbides are not used as hard materials, although they do have some metallic character. Other saltlike carbides do not have industrial importance.

The carbides B_4C and SiC are used in large quantities as abrasives (→ Abrasives; → Boron Carbide, Boron Nitride, and Metal Borides, → Silicon Carbide). Heating elements and many heat-resistant parts are made from SiC.

2. Metal-like Carbides of Industrial Importance

The important individual carbides of the transition metals and the mixed carbides of these metals are described in detail in the following. Tungsten carbide, WC, because of its importance in cemented carbides, or hardmetals, is described first. Thereafter, TiC, TaC, and NbC, which are also basic hard carbides, are described. The physical properties of these four carbides are given in Table 1. Finally, the carbides of Zr, Hf, V, Cr, and Mo are described. These last carbides are used only as additives in cemented carbides and have less importance. Their physical properties are given in Table 2.

2.1. Tungsten Carbide

There are two hexagonal carbides in the tungsten – carbon system (Fig. 2): the monocarbide, WC, and the subcarbide [*12070-13-2*], W_2C. The hexagonal WC, also called α-WC, decomposes at its incongruent melting point of 2776 °C. Its range of homogeneity is extremely narrow: from 49.5 to 50.5 mol % C.

∗ Properties given without a temperature are for room temperature.

The subcarbide, W_2C, probably has three modifications. The highest temperature modification melts without decomposition at ≈ 2800 °C. The "eutectic" of W_2C and WC is known as cast or fused tungsten carbide. The solid eutectic mixture is sometimes incorrectly called W_2C. In addition to these two industrial carbides, there is a substoichiometric face-centered cubic WC_{1-x} phase, also called β-WC, which is unstable at room temperature, forming only above 2530 °C. The phase diagram is made more complicated by this additional compound and the W_2C modifications, mainly in the high-temperature range. Although many have investigated the tungsten – carbon system, unanswered questions remain.

Figure 2. Tungsten – carbon phase diagram

Properties. Commercial monocarbide, WC, the raw material for the powder-metallurgy industry, is a gray metallic powder. Its average grain size is between 0.5 and 20 µm. In addition, very small quantities are prepared with smaller or coarser size for special applications. The carbide is insoluble in water and dilute acids, but is dissolved by hot mixtures of HNO_3 and HF. It is oxidized in air above 600 °C. Although it is stable in dry hydrogen up to its melting temperature, wet hydrogen decarburizes it. Chlorine attacks WC above 400 °C, while fluorine attacks WC at room temperature.

Hardness, combined with high modulus of elasticity, is the most important mechanical property of WC. The microhardness is anisotropic [10], [11] and, because of this, values ranging between 1000 and 2500 kg/mm^2 can be found in the literature.

The chemical resistance of the subcarbide W_2C is less than that of WC. The subcarbide is dissolved by HNO_3 – HF mixtures even at room temperature. It may be distinguished from WC by its reaction with alkaline potassium hexacyanoferrate (Murakami's reagent): W_2C turns yellow to brown, whereas WC remains gray. The microhardness of the subcarbide is higher than that of WC, but W_2C is not used alone industrially because it is too brittle.

Because eutectic W_2C – WC is prepared by a fusion process, it is not produced as a powder in the micron range. The grains are much coarser, up to several millimeters. The carbon content can vary from 3.5 to 4.5 wt %, corresponding to 50 – 90 % of W_2C or 10 – 50 % of WC in this "eutectic".

Preparation. Most of the world's annual production of 15 000 – 20 000 t of WC is made by direct carburization of tungsten metal with carbon. Mixtures of metal and lamp black, or even graphite, are heated to temperatures between 1400 and 2000 °C in a hydrogen atmosphere or vacuum. Electrical walking-beam or pusher-type furnaces or gas-fired muffle furnaces are used. Carbon tube furnaces are needed for the high-temperature range, and batch-type induction furnaces are needed for vacuum processing.

After purity, the most important property of the carbide is grain size, because the grain size significantly affects the mechanical properties of WC products. Fine-grained powders cannot be made from coarser powders only by milling. Intensive milling changes carbon and oxygen contents, the shape of the grains, and the grain size distribution. Therefore, the grain size is better determined by the processing parameters during reduction and carburization: temperature, reaction time, humidity, flow rate of the hydrogen, and several other factors. Most importantly, the grain size of the starting material must be selected to produce the desired end product. Generally, powders become coarser when converted from oxide to metal to carbide.

The chemical nature of the starting materials and the intermediate steps also affect the physical properties of the final carbide. Possible starting materials are tungstic acid [*7783-03-1*], H_2WO_4, and ammonium paratungstate or APT [*11120-25-5*], $(NH_4)_{10}W_{12}O_{41} \cdot 5H_2O$. The intermediates are yellow oxide (WO_3), blue oxide (W_4O_{11}, simplified), and brown oxide (WO_2). Various ways of processing are illustrated in Figure 3 by the flow sheet, which contains 12 different production lines.

Figure 3. Various production lines leading to WC
APT stands for ammonium paratungstate

The following are typical production lines:

1) Fine tungstic acid powder is reduced directly to metal by dry hydrogen at 750 °C. Metal particles with an average size of 0.7 – 0.8 µm are obtained. These are carburized at 1400 °C to produce 1-µm carbide.
2) Ammonium paratungstate is calcined at 700 °C in a stream of nitrogen to give blue oxide, which is reduced at 800 °C. The metal is carburized at 1400 °C to produce carbide of 2 – 5 µm.
3) Ammonium paratungstate is roasted at 800 °C in air to produce WO_3. This is reduced by wet hydrogen at 950 °C. Carburizing at 1600 °C produces carbide of 10 – 20 µm.

Tungsten oxides can also be carburized directly with carbon, e.g.,

$$WO_3 + 4\,C \longrightarrow WC + 3\,CO$$

In this case, the intermediate metal step is omitted. The disadvantage is the difficulty in obtaining the correct carbon content in the carbide, since the CO itself reacts with oxide to form metal to a degree that cannot be calculated. Therefore, this process is used only to produce technical grades. Tungstic acid, ammonium paratungstate, or even scheelite (natural or artificial) can be treated in the same way.

$$CaWO_4 + 4\,C \xrightarrow{1800\,^\circ C} CaO + 3\,CO + WC$$

However, when scheelite is heated with carbon, the resulting cake must be leached with acid to isolate the carbide, and this carbide is of low quality because of its high level of impurities.

Tungsten metal can be carburized by carbon-containing gases, usually carbon monoxide or methane. Gas-phase carburization is done preferably in the temperature range 800 – 900 °C. Therefore, the grains do not become much coarser. For example, WC of 0.3 – 0.4 µm is obtained from 0.3-µm metal. Such fine carbides are often called submicron carbides. Tungsten oxide can also be reduced and carburized in one step by CO or CH_4, but the product is always slightly deficient in combined carbon. When CO is used, water is not present in the furnace atmosphere as a byproduct of reduction. Because grain growth of tungsten during reduction is induced mainly by water vapor and high temperature, extremely fine WC can be made. These powders can be used as catalysts in fuel cells.

Another method of preparing fine WC is the reaction of tungsten metal or oxide with CH_4 and H_2 in a plasma reactor [12]. Carbide having a grain size of 0.1 µm or less, sometimes called ultrafine carbide, is obtained. The plasma technology and the use of such ultrafine WC are still being developed.

Numerous other ways to prepare WC have been developed. Some are modifications of the processes just described; others are entirely different. Most still need to be improved and are not yet in use on an industrial scale:

1) In the Axel – Johnson process, tungsten ore, ferrotungsten, or tungsten scrap is treated with chlorine to form WCl_6, which is reduced by H_2 in a gas-phase reaction. The fine metal formed by this reaction is carburized by a conventional process [13].
2) A mixture of WO_3 and carbon is heated in a two-stage rotary furnace. In the first stage the oxide is reduced to metal in a stream of nitrogen, and in the second stage WC is formed at higher temperature in a stream of hydrogen [14].
3) A mixture of WO_3, Co_3O_4, and carbon is reduced in H_2. After carburization, the mixture of WC and cobalt metal can be sintered directly to cemented carbides. The WC grains have a uniform, fine size, which is a result of the coreduction of the oxides [15].

All methods of preparation described thus far are solid-state or gas-phase reactions. The preparation of cast tungsten carbide is the only method involving fusion. A mixture of tungsten metal and carbon or tungsten carbide is heated in a carbon tube or high-frequency furnace to ca. 2800 °C. The molten eutectic is quenched in

water or otherwise cooled rapidly to produce a fine crystalline structure.

Uses. Tungsten carbide is by far the carbide most used in cemented carbides: About 90 % of the world's production of carbide tools are tungsten carbide-based sinter alloys. Of these, 50 % are so-called straight grades, tungsten carbide – cobalt products consisting of 70 – 95 wt % of tungsten carbide. There are many, many uses for cemented carbides of various compositions. The greatest demand is for cutting and drilling tools, mining machinery, and wear-resistant parts of all kinds. Some examples illustrate the broad field of applications: milling cutters, cutting tips and drills, sawing teeth and blades, drawing and heading dies, rolls, nozzles, sealing rings, balls for ball mills, balls for ballpoint pens, tire studs, and even scratch-proof watchcases. Protective surface coatings are made from cast tungsten carbide.

The mechanical properties of the cemented carbides depend primarily on the grain size of the tungsten carbide. Generally speaking, smaller grain sizes produce greater hardness but lower crack resistance. The cobalt content also affects the mechanical properties, and the properties of the cemented carbide can be adjusted to the mechanical requirements over a wide range.

Toxicology. Tungsten carbide and the other carbides of the transition metals are not known to be toxic in themselves. However, nearly all of these carbides are used in combination with cobalt metal, and cobalt dust is carcinogenic. Therefore, mixtures for the powder-metallurgical preparation of cemented carbides are classified as dangerous materials in some countries.

2.2. Titanium Carbide

The face-centered cubic monocarbide TiC is the only carbide in the titanium – carbon system. It melts without decomposition at ca. 3000 °C. Its range of homogeneity is very broad, ranging from 35 mol % to just below 50 mol % carbon. The composition with the highest melting point and the largest lattice constant contains less carbon than stoichiometric TiC (see Fig. 4). Because of this, undesired low-carbon phases cannot be formed during sintering of cemented carbides when TiC is present, unlike the case for the straight WC – Co grades. Titanium carbide forms solid solutions with all other cubic transition-metal carbides of groups 4 and 5. In addition, it is the host lattice for hexagonal WC in the most important industrial solid-solution carbide, (W,Ti)C (see Section 3.1).

Figure 4. Titanium – carbon phase diagram [3]

At elevated temperatures, TiC and Ti metal react with oxygen and nitrogen to form TiO and TiN, the structures of which are isotypical to the lattice of TiC. Therefore, many TiC powders contain small amounts of N and O, to an extent of 1 % or more, and may be viewed as Ti(C, N, O) mixed crystals.

Commercial TiC is a gray powder usually having an average grain size of 2 – 10 µm. It is very resistant to acids, oxidation, and heat. However, it is dissolved easily by mixtures of HNO_3 and HF. In hydrogen it can be heated to its melting point without decomposition. Titanium carbide is the hardest of all the transition-metal carbides.

Preparation. Most commercial TiC is made by the reaction of TiO_2 with carbon. Intimate mixtures of pure TiO_2 and carbon are heated

to 2000 °C or above in a hydrogen atmosphere. Large quantities of CO are produced. After the resulting cake is milled, the material contains up to 1 wt % each of free carbon, nitrogen, and oxygen. The amounts of these elements must be reduced in a second step, usually a vacuum heating process. Nitrogen and oxygen contents are decreased to less than 0.1 wt % each. The free carbon content is usually in the range 0.2 – 0.4 wt %, and the combined carbon is 19.5 wt % max., somewhat less than the stoichiometric content of 20.05 wt %.

Titanium metal can be carburized with carbon. Titanium sponge, or even finely divided scrap, is used. The process is exothermic, and therefore, exact temperature control is not possible. As a result, the cake is sometimes extremely dense and can merely be broken down or milled only with difficulty. Carbon, nitrogen, and oxygen contents must be adjusted in a subsequent process.

Very coarse, comparatively pure TiC is prepared by the auxiliary metal bath technique [16]. Titanium metal, ferrotitanium, or even titanium alloy scrap is dissolved along with graphite in molten metal, preferably iron or nickel. After this mixture is cooled, TiC is isolated by dissolving the auxiliary metal with a nonoxidizing acid (menstruum process).

Extremely fine TiC is made in a plasma reaction of $TiCl_4$, H_2, and CH_4.

Layers of TiC on other materials may be produced by controlled vapor deposition from a mixture of $TiCl_4$, H_2, and CH_4.

Uses. Titanium carbide is the hardest carbide of the commercial transition-metal carbides, but it is too brittle to be used alone. However, it is the most important additional carbide in tungsten-based cemented carbides for cutting steel. Although toughness is decreased a little by the addition of TiC, the hardness and especially the heat resistance are increased significantly. Normal steel-cutting grades contain 5 – 30 wt % of TiC. Furthermore, TiC is the basic carbide for the formation of solid solutions with all other transition-metal carbides used in cemented carbides. In tungsten-free hardmetals, TiC is used in combination with molybdenum carbide and nickel binder metal.

Titanium carbide in combination with steel alloy forms a special type of hard alloy called Ferro-TiC. Tungsten-based cemented carbides can be replaced by this material in some cases. TiC was the first carbide material used for coatings on cutting tips made from normal cemented carbides. Even though the thickness of such a layer is in the range of only a few microns, the life of the cutting tools is increased markedly. Some TiC is used in combination with oxides in ceramic cutting tools (Al_2O_3 – TiC).

2.3. Tantalum Carbide

Figure 5. Tantalum – carbon phase diagram [3]

In general, the phase relationships in the systems of group 5 metals and carbon are complex. The system Ta – C (Fig. 5) is typical for the group. This system is characterized by several subcarbides, with lower carbon contents, in addition to the monocarbide, TaC. The face-centered cubic monocarbide melts without decomposition near 4000 °C, one of the highest melting points known. The broad range of homogeneity extends from 43 to 50 mol % C. The subcarbide Ta_2C decomposes at its incongruent melting point. There are two modifications, a high-temperature phase, with disordered L′3 structure, and a low-temperature phase,

of C6 type. The transformation temperature is near 2000 °C. In addition, there is a metastable Ta_3C_2, which is sometimes called the Brauer or ζ-phase. Similar phases are also found in the V – C and Nb – C systems, although the structure of the carbides is still not completely resolved [17].

The monocarbide, TaC, is the only phase of commercial interest. It is a brown powder, usually of 1 – 5 µm average grain size. Sintered and polished pieces have a yellow-golden sheen. The chemical resistance is high. The monocarbide is stable in nonoxidizing acids, although it is attacked easily by a mixture of HNO_3 and HF and by oxidizing salt melts. It can be heated up to 3000 °C in hydrogen or nitrogen, but it is oxidized rapidly in air at 800 °C.

Preparation. The method most used for preparation is based on the reaction of tantalum oxide with carbon:

$$Ta_2O_5 + 7\,C \longrightarrow 2\,TaC + 5\,CO$$

Intimate mixtures of oxide and carbon are pressed into graphite boats and heated at 1700 °C in hydrogen. Usually the product is deficient in bound carbon, and this must be adjusted in a second step. Tantalum metal can also be used for direct carburization with carbon. Very pure monocarbide for scientific use is obtained by the reaction of tantalum hydride with carbon.

A commercial grade of lower purity can be made by melting ferrotantalum or tantalum-containing scrap and slag in a metal bath with an excess of carbon. After the mixture is cooled, the auxiliary metal is dissolved with acid to free tantalum carbide. An additional step to adjust the carbon content is also necessary in this process.

Uses. Because of its extremely high melting point, some TaC is used in high-temperature techniques, but the main application is in hardmetals. Although TaC is the most expensive of all the carbides normally used in cemented carbides, consumption is still increasing because of the marked improvement in the properties of cemented carbides containing TaC. The world's annual demand can be estimated to be ca. 500 t.

There are two quite different reasons for this use of TaC. First, small amounts of TaC, in the range of 0.2 – 2.0 wt %, are added to straight WC – Co grades in which fine-grained WC, 1.5 µm or less, is used. In these grades, often there is an undesired grain growth of the carbide phase during sintering because of the sintering time and temperature and probably some still unknown factors. This grain growth is inhibited to a great extent by TaC. Although there are other, cheaper compounds that retard grain growth, TaC is preferred because it is the only compound known to have no negative effects. The second reason for using TaC in cemented carbides is based on the great improvement in cutting tools, mainly in long-chipping steel cutting grades. In this second case the TaC content ranges from 2 to 15 wt %, and even more in some special cases. Thermal shock resistance, hot hardness, and resistance against cratering and oxidation are all increased markedly.

2.4. Niobium Carbide

The phase relationships in the system niobium – carbon are quite similar to those in the system tantalum – carbon. However, because of the close similarity, there is some doubt about the correctness of the phase diagram. The face-centered cubic monocarbide, NbC, melts without decomposition at ca. 3600 °C. It has a range of homogeneity from ca. 40 to almost 50 mol %; the stoichiometric value of 50 % is never reached. The subcarbide Nb_2C decomposes at its melting point of ca. 3000 °C. It exists in several modifications, the number and structure of which are a point of uncertainty. The other open question is the existence of an additional ζ-phase, Nb_3C_2.

The monocarbide, NbC, is the only phase used industrially. It is a gray-brown powder of normally less than 10 µm average grain size. Sintered pieces show a lavender tint. The chemical reactivity is similar to that of TaC, but NbC is less resistant to nitrogen. Heating the carbide in ammonia produces the nitride.

Preparation. Niobium monocarbide, NbC, is made in the same way as TaC: by carburization of the oxide, hydride, or metal at 1500 °C. The auxiliary metal bath technique can also be used. Most NbC is not produced as a single pure compound because demand for pure NbC

is small. Nearly all of the NbC is used in combination with TaC; therefore, mixtures of Nb_2O_5 and Ta_2O_5, in various ratios, are carburized together. The resulting products are true mixed crystals of NbC and TaC. Any ratio can be prepared, but the usual commercial compositions contain 10, 20, or 50 wt % NbC.

Uses. Only small quantities of pure NbC are needed. Some is used in special grades of cemented carbides in combination with Al_2O_3 (cermets). Another use is the reduction of Nb_2O_5 by NbC to niobium metal, a process carried out at 1600 °C under vacuum or hydrogen.

Most of the NbC is used in combination with TaC in hardmetals. When used with TaC, the NbC improves the properties of the sintered material just like pure TaC does. At the same time, NbC is much less expensive than TaC. However, NbC is said to decrease the strength when it is added in large amounts. The limit and the degree of toughness loss are not known exactly. In any case, NbC is never used alone, and the content of NbC in the TaC ranges from less than 1 to 50 wt %.

2.5. Zirconium Carbide

The monocarbide ZrC is the only compound in the zirconium – carbon system. It has a face-centered cubic crystal structure, and the range of homogeneity reaches from 38 to 50 mol % C. Zirconium carbide melts without decomposition at ca. 3400 °C. The phase boundaries in the Zr – C system are extremely sensitive to oxygen, nitrogen, and probably even more to other impurities. On the other hand, ZrC is difficult to prepare free from oxygen and nitrogen because the lattices of ZrC, ZrO, and ZrN are isotypical. As a result there have been many misinterpretations of the phase diagram in the past, and some disagreements still must be clarified.

The carbide is a gray powder. Its chemical resistance is somewhat lower than that of TiC. It is dissolved by cold HNO_3 or a cold mixture of H_3PO_4 and dilute H_2SO_4. It can be heated in hydrogen up to its melting point, but it is attacked by oxygen at 500 °C. When the carbide is heated in nitrogen above 1500 °C, the nitride is formed.

Preparation. Zirconium carbide is made mostly by heating mixtures of ZrO_2 and carbon at 1800 – 2400 °C in hydrogen or under vacuum. The carbon content must be adjusted in a second step. The metal, in the form of a sponge, or the hydride can be carburized with carbon at a temperature as low as 1400 – 1600 °C. Up to 1800 °C, the carbide getters oxygen, and oxygen-free material is difficult to obtain. Very pure ZrC, for scientific use, can be made by the gas-phase reaction of $ZrCl_4$, H_2, and a hydrocarbon.

Use. Up to now only small quantities of ZrC have been used in hardmetals. This may be due to the comparatively high price of ZrC as well as to its insufficient heat resistance. ZrC forms solid solutions with all other transition-metal carbides. Therefore, the demand of ZrC may increase. Other than use in cemented carbides, there is no use of importance.

2.6. Hafnium Carbide

The hafnium – carbon system and the properties of the carbide are similar to those of zirconium. The only phase is the face-centered cubic monocarbide, HfC. The broad range of homogeneity extends from 37.5 to 50 mol % C. The carbide melts at ca. 3900 °C without decomposition. Its chemical reactivity seems to be similar to that of ZrC, but little information is to be found in the literature.

Preparation. Hafnium dioxide can be carburized like ZrO_2 in hydrogen or under vacuum at 1800 – 2200 °C. If hafnium metal or hydride is used for carburization, a temperature of 1600 – 1700 °C is sufficient. When the oxide is the starting material, a second step for adjustment of carbon content and reduction of the oxygen content is necessary. This second step is often not neces-sary if the metal or hydride is the starting material.

Uses. Hafnium oxide or metal is a byproduct in the production of zirconium for nuclear reactors. Therefore, hafnium is available in sufficient quantities, and HfC has become attractive for cemented carbides. Tantalum carbide, TaC,

in steel-cutting tools or as grain-growth inhibitor may be replaced by HfC. An HfC – NbC solid solution seems to be the most effective. Coatings of HfC on normal hardmetal tools increase the oxidation resistance. Such coatings are made by chemical vapor deposition (CVD) with $HfCl_4$ and a carbonizing gas.

2.7. Vanadium Carbide

Vanadium forms the same phases with carbon as tantalum and niobium. The face-centered cubic monocarbide, VC, exists over a broad range of homogeneity, from 43 to 49 mol % C. It melts without decomposition at ca. 2800 °C. There are two modifications of the subcarbide, V_2C, the orthorhombic low-temperature α-phase and the hexagonal high-temperature β-phase. The latter decomposes on melting. Furthermore, there is a metastable ζ-phase, V_3C_2. Often a V_4C_3 phase has been described in the literature, but this phase is only found in vanadium-containing steel alloys. Probably it is not a distinct phase, but rather a solid solution of carbide, oxide, and nitride, the structures of which are isotypical.

The only phase of commercial interest is the monocarbide, VC. It is a gray powder with a grain size usually of several micrometers. It is resistant to cold acids, except HNO_3, but it is easily dissolved by hot oxidizing acids. The monocarbide can be heated to its melting point in hydrogen, but in air it is oxidized rapidly at 800 °C.

Preparation. Vanadium monocarbide is made mostly by heating V_2O_3 or V_2O_5 with carbon at 1500 – 1700 °C in hydrogen. Ammonium vanadate also can be used as the starting material. A second treatment under vacuum is necessary in every case to adjust the carbon content and to reduce the oxygen level. Because of the great stability of the V(C,O,N) mixed crystal, oxygen-free material is difficult to prepare. Very pure VC is best made by the reaction of vanadium metal with carbon under vacuum.

Uses. Vanadium monocarbide is too brittle to be used alone in cemented carbides. Some special grades were made with VC – TiC mixed crystals with nickel or iron binder, but this was done temporarily only when there was a shortage of tungsten. Small quantities of VC are used to inhibit grain growth in tungsten carbide – cobalt hardmetals. The effectiveness is higher than that of TaC, but the toughness of the sintered material is lower when > 0.5 % VC is added. Large quantities of VC are contained in steel alloys where it forms during melting.

2.8. Chromium Carbide

The phase relationships in the chromium – carbon system are quite different from those of the other metals of group 6 as well as those of the metals of groups 4 and 5. Hägg's ratio of the atomic radii is 0.609 in the case of chromium and carbon; thus, the critical figure of 0.59 is exceeded and a simple closest packed structure can no longer form. There are three chromium carbides in the system (Fig. 6). The cubic carbide $Cr_{23}C_6$ [*12105-81-6*] is a complex $D8_4$ type with 116 atoms in the unit cell. It decomposes on melt-ing at ca. 1500 °C. This $Cr_{23}C_6$ is sometimes formulated incorrectly as Cr_4C. The hexagonal Cr_7C_3 [*12075-40-0*] melts without decomposition at ca. 1800 °C, whereas the orthorhombic Cr_3C_2 [*12012-35-0*] decomposes at its melting temperature of ca. 1900 °C. All three phases have very narrow ranges of homogeneity. There are hints of the existence of one or more additional phases in the high-temperature range. These phases and some uncertainties in the phase boundaries between the known carbides are still a matter of discussion. Very little is known about the properties of $Cr_{23}C_6$ and Cr_7C_3 because these carbides are not prepared as pure compounds and are never used alone. They form during melting of steel and ferrous alloys, and they exist probably in the form of mixed crystals with iron and other metallic carbides. The carbide Cr_3C_2 is the only phase produced as such. It is a gray powder of a grain size normally less than 10 µm. It is insoluble in cold HCl, but dissolves in hot oxidizing acids and in H_2O_2. It has the greatest resistance to oxidation of all metal-like carbides. It is stable in air up to 1000 °C because of a very dense and firm oxide layer that forms on its surface.

Preparation. The carbide Cr_3C_2 is made by heating mixtures of Cr_2O_3 and carbon up to 1600 °C in hydrogen. Below 1300 °C, primarily Cr_7C_3 is formed. The following equations

Figure 6. Chromium – carbon phase diagram [6]

demonstrate how complicated the process of carburization is:

$$3\,Cr_2O_3 + 13\,C \longrightarrow 2\,Cr_3C_2 + 9\,CO$$

$$5\,Cr_2O_3 + 27\,Cr_3C_2 \longrightarrow 13\,Cr_7C_3 + 15\,CO$$

$$Cr_2O_3 + 3\,Cr_7C_3 \longrightarrow Cr_{23}C_6 + 3\,CO$$

$$2\,Cr_2O_3 + 3\,Cr_3C_2 \longrightarrow 13\,Cr + 6\,CO$$

Oxygen-free Cr_3C_2 with the stoichiometric carbon content is difficult to obtain if the starting material is the oxide. Very pure Cr_3C_2 can be made by the carburization of chromium metal powder.

Uses. Some Cr_3C_2 is used in hardmetals in special tools with great resistance to acids and salts. In these grades the carbide is bound with nickel. Small quantities of Cr_3C_2 are used as a grain-growth inhibitor in WC – Co cemented carbides. Considerable amounts of the eutectic $Cr_7C_3 - Cr_3C_2$ are used in welding electrodes for hard facing.

The greatest demand for chromium carbides is in steel, Stellites, and related alloys. In such cases, pure chromium carbides are not used; instead, chromium metal is added to the melt together with carbon-containing additives.

2.9. Molybdenum Carbide

Although much work has been done on the molybdenum – carbon system, there are still uncertainties and disagreements. The existence of at least four phases seems to be assured (Fig. 7). The hexagonal Mo_2C is the only phase stable at room temperature. Its range of homogeneity is very narrow and lies between 33 and 34 mol % C. The orthorhombic Mo_2C phase is stable only above 1475 °C. It melts without decomposition at ca. 2400 °C. Two carbon-rich phases, ca. 39 mol % C, exist only at high temperature, a hexagonal one above 1655 °C and a cubic one above 1960 °C. Both phases are designated as MoC_{1-x} by some authors and as MoC or Mo_3C_2 by other authors. Below their decomposition temperatures these phases break down into Mo_2C and C. Hexagonal MoC_{1-x} is isotypical with WC and can be stabilized by the inclusion of tungsten. More phases have been observed in the system, but probably all of them were oxygen-containing mixed phases.

The only phase of commercial interest is the hexagonal Mo_2C. It is a gray powder in the micron range. It is resistant to nonoxidizing acids but is dissolved by HNO_3 or by hot H_2SO_4. It

Figure 7. Molybdenum – carbon phase diagram [6]

is stable in hydrogen, but it is oxidized in air at 500 °C.

Preparation. Although MoO_3 or MoO_2 can be carburized with carbon at 1500 °C, a carbide with the correct carbon content and a low oxygen content is difficult to obtain. Pure Mo_2C is best made by heating molybdenum metal powder with carbon in hydrogen at ca. 1500 °C.

Uses. Mo_2C is used in special cemented carbide grades containing TiC and nickel metal. Such grades were the first tungsten-free hardmetals. Attempts have been made to replace tungsten partially with Mo – W mixed crystals. Most Mo_2C is used in steel alloys, where it forms during melting.

3. Mixed Carbides

The commercial carbides of groups 4, 5, and 6 form numerous mixed carbides with each other. The formation of these solid solutions depends on the lattice constants of the carbides and corresponds to the Hume – Rothery rule on the atomic volumes. Only a few of the metallic carbides do not conform to these conditions and, thus, do not form a continuous series of solid solutions. The cubic monocarbides of the metals of groups 4 and 5 are completely miscible, except the pairs ZrC – VC and HfC – VC, which are soluble in each other only to a limited extent. Limited miscibility is found between TiC and the carbides of Cr, Mo, and W, but there are still some uncertainties about the TiC – WC system. Solid solutions of three or more carbides also exist. The host lattice of the mixed carbides is usually TiC. The

hexagonal WC has only a negligible capability to receive cubic carbides into solid solution.

The use of mixed crystals in cemented carbides offers several advantages. Mixed crystals are harder and tougher than single, unalloyed carbides. The contents of oxygen, nitrogen, and free graphite are distinctly lowered by autopurification during the diffusion process; the wettability by cobalt and other binder metals is increased.

The temperatures for the preparation of mixed crystals are ca. 500 °C higher than the normal sintering temperatures for hardmetals. Therefore, an exact formation of mixed crystals cannot be attained by mixing the individual carbides with the binder metal before sintering: the mixed carbides must be prepared in a separate process.

The mixed carbides can be prepared by the processes used for the preparation of the single carbides. Mixtures of the oxides and carbon are heated up to 1800 – 2000 °C in hydrogen, mostly in high-frequency induction furnaces. A second step under vacuum is always necessary to adjust the carbon content. The mixed metal powders can be treated with carbon in the same way. In addition, the reaction of metal oxide with another metal carbide and additional carbon is used, for example:

$$TiO_2 + WC + 3\,C \longrightarrow 2\,(Ti,W)C + 2\,CO$$

Very pure mixed carbides are best made by heating mixtures of the single carbides at 2000 °C under vacuum. The process of diffusion can be accelerated by the addition of cobalt, nickel, iron, or chromium metal in the range 0.5 – 1.0 wt %:

$$TiC + TaC \xrightarrow{Ni} 2\,(Ti,Ta)C$$

Pure mixed crystals are also made by the auxiliary metal bath technique (menstruum process, see page 9).

3.1. Tungsten – Titanium Carbide

The most important mixed carbide in cemented carbides is tungsten – titanium carbide. The ternary system is not yet known in all its details. The uncertainties in the Ti – C system caused by the isotypical TiO and TiN phases are observed in the Ti – W – C system as well. The solid solubility of WC in the cubic lattice of TiC is limited and depends on the temperature:

Temperature, °C	1500	2000	2400
WC, wt %	60	80	90
WC, mol %	31	55	73

Above 2600 °C, there is probably complete miscibility.

Saturated mixed crystals prepared at high temperatures become supersaturated when used in hardmetal production because of the comparatively low sintering temperatures, only 1400 – 1500 °C. Therefore, very fine WC crystals precipitate in the metal binder phase, thus strongly influencing the properties of the hardmetal. The mechanisms are still a matter of discussion. The W – Ti mixed crystals used in industry generally contain 50 or 70 wt % W.

3.2. Other Mixed Carbides

Another important mixed carbide for cemented carbides is tungsten – tantalum carbide. The solubility of cubic TaC in hexagonal WC is negligible, but WC has a limited solubility in TaC that depends strongly on the temperature:

Temperature, °C	1500	1800	2000	2500
WC, wt %	10	20	27	70

Because the solubility of WC in TaC decreases rapidly as the temperature is lowered, WC crystals always precipitate from the solid solutions during cooling. Therefore, preparation of single-phase (W,Ta)C mixed crystals is almost impossible, and unlike other mixed carbides, (W, Ta) C is usually marketed with the additional designation *double phase.*

The (W,Ti,Ta)C mixed crystal may be viewed as a combination of (W,Ti)C and (W,Ta)C mixed crystals. It is used in considerable quantities in cutting tools for steel and related long-chipping materials. Sometimes this mixed crystal is called "triple carbide", which is incorrect because in nearly every case, TaC – NbC mixtures, not pure TaC, are used. The system W – Ti – Ta – Nb – C is not yet known in all its details. There are some

isothermal sections in the quasiternary system WC – TiC – TaC [18], but the effects of the addition of NbC to this system are not known exactly.

Another important mixed crystal is titanium – molybdenum carbide (Ti,Mo)C. It is used in tungsten-free hardmetals with nickel binder for special steel cutting tools.

From the nine commercial carbides of the transition metals, 36 combinations of double carbides can be formed. Some of these are attracting growing interest, for example (W,Mo)C as a partial substitute for WC, or (Zr,Hf)C and (Zr,Nb)C as substitutes for TaC. All the double carbides are being intensively investigated [19], [20]. Mixed crystals of three transition-metal carbides, such as (Ti,Nb,Ta)C, number a total of 84, and 126 combinations are possible from four carbides, for example, (Ti,W,Hf,Zr)C. The knowledge about most of these systems is still quite limited.

3.3. Carbonitrides

The face-centered cubic monocarbides of groups 4 and 5 are isotypical with the face-centered cubic nitrides of the same groups, and because of this, there is complete miscibility between a metal carbide and metal nitride. The situation for Ta (C,N) is more complex because the usual form of TaN is hexagonal, the cubic TaN being stable only at high temperature and pressure.

With some limitations all carbonitride compounds can be used in cemented carbides [21]. A special application is scratchproof watchcases, because some carbonitrides are colored. The tint depends on the C : N ratio. For example, Nb (C,N) is violet at high carbon contents but yellow at high nitrogen contents. Another special application is coating of normal cemented carbides with layers of carbonitrides, usually Ti (C,N), by chemical vapor deposition (CVD). Carbonitrides can best be made by heating mixtures of the single carbides and nitrides in argon or under vacuum at 1600 – 1800 °C.

3.4. Mixed Carbonitrides

By methods similar to those used in the production of solid solutions of carbides or carbonitrides, a large number of mixed crystals can be prepared with various metals and nonmetals in one lattice. Only a few of them have been investigated up to now, and still fewer are used commercially. However, interest is growing. For example, (W,Mo)(C,N) with a nickel binder has properties comparable to those of WC – Co cemented carbides and can be used as a partial substitute for tungsten. The mixed carbonitride (Ti,Mo)(C,N) with a nickel alloy binder can be made to have an extremely fine carbide structure because of a spinodal decomposition of the carbonitrides. Both (Ti,W)(C,N) and (Ti,Ta)(C,N) have excellent heat-resistant properties.

4. Carbides of the Iron Group and Manganese

The carbides of Fe, Co, Ni, and Mn are usually classified as metallic carbides or metal-like carbides like the carbides of groups 4, 5, and 6. However, in fact, they are different from the transition-metal carbides, and their metallic characteristics are less pronounced. Hardness, melting points, and electrical conductivity are all distinctly lower. The crystal structures are not the simple interstitial Hägg phases, but rather much more complex structures, similar to those of the chromium carbides.

The carbides of Fe, Co, Ni, and Mn are neither prepared nor used alone. They are formed in iron and steel alloys during the melting process, and they can be isolated from these products by anodic oxidation of the metals. The carbides are important because they are the hardening phases in steel alloys, Stellites, cast iron, and related materials.

In the iron – carbon system there is probably only one phase, the orthorhombic Fe_3C, which is called cementite [*12011-67-5*]. Preparation of the pure carbide from the elements has not been achieved up to now. When Fe_3C is isolated electrolytically from alloys and sintered with cobalt metal, it decomposes. In alloy steels, the "iron carbide" is mostly included in mixed crystals with chromium carbides: $(Fe,Cr)_{23}C_6$, $(Fe,Cr)_7C_3$, and $(Fe,Cr)_3C_2$.

Cobalt and nickel form only the carbides Co_3C and Ni_3C, which are isotypical to Fe_3C. In the manganese – carbon system, three carbides

are formed: Mn_3C is isotypical to Fe_3C, and Mn_7C_3 and $Mn_{23}C_6$ are isotypical to the corresponding chromium carbides.

5. Complex Carbides

A great number of ternary and quaternary phases can be formed between carbon and two or three metals, one a transition metal. In addition, the elements S, P, and As can be included.

These so-called complex carbides are a group of their own. They are not solid solutions of one carbide in the lattice of another carbide. Each has its own typical structure, which in all cases is much more complicated than the simple Hägg phases of the transition-metal carbides.

Numerous complex carbides have been investigated [9], and all were found to contain octahedral or, less often, trigonal prismatic M_6C groups. M is always a transition metal, and six such atoms surround a central carbon atom. The octahedrons are linked by common corners, edges, or faces. The resulting interstitial sites can be occupied by other metals. Many distinct crystal structures can be formed under these conditions. The most important are perowskite carbides such as Ti_3AlC, β-Mn carbides such as Ta_3Al_2C, $\varkappa$-carbides such as $W_{16}Ni_3C_6$, η-carbides such as W_3Co_3C, H-phases or Cr_2AlC-type carbides such as Zr_2SC, V_3AsC-type carbides such as Cr_3PC, and Mn_5Si_3-type carbides such as $Nb_5Ga_3C_{0.2}$. Complex carbides can be best prepared by heating mixtures of the single carbides and metals for an extended period of time. Mechanical pressure or gas pressure is helpful.

Of commercial interest are mainly the η-carbides, which are formed in alloy steels and in Stellites. In hardmetals, η-carbides, such as W_3Co_3C and W_4Co_2C, form because of carbon deficiency, these phases causing a decrease in toughness.

1. Introduction

Terrestrial biomass constitutes a multifaceted conglomeration of low and high molecular mass products, exemplified by sugars, hydroxy and amino acids, lipids, and biopolymers such as cellulose, hemicelluloses, chitin, starch, lignin and proteins. By far the most abundant group of these organic products and materials, in fact about two thirds of the annually renewable biomass, are carbohydrates, i.e., a single class of natural products. As the term 'carbohydrate' (German *'Kohlenhydrate'*; French *'hydrates de carbone'*) implies, they were originally considered to consist solely of carbon and water in a 1:1 ratio, in recognition of the fact that the empirical composition of monosaccharides can be expressed as $C_n(H_2O)_n$. Today, however, the term is used generically in a much wider sense, not only comprising polysaccharides, oligosaccharides, and monosaccharides, but substances derived thereof by reduction of the carbonyl group (alditols), by oxidation of one or more terminal groups to carboxylic acids, or by replacement of one or more hydroxyl group(s) by a hydrogen atom, an amino group, a thiol group, or similar heteroatomic groups. A similarly broad meaning applies to the word 'sugar', which is often used as a synonym for 'monosaccharide', but may also be applied to simple compounds containing more than one monosaccharide unit. Indeed, in everyday usage 'sugar' signifies table sugar, which is sucrose (German *'Saccharose'*; French *'sucrose'* or *'saccharose'*), a disaccharide composed of the two monosaccharides D-glucose and D-fructose.

Carbohydrates appear at an early stage in the conversion of carbon dioxide into organic compounds by plants, which build up carbohydrates from carbon dioxide and water by photosynthesis. Animals have no way of synthesizing carbo-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a05_079

hydrates from carbon dioxide and rely on plants for their supply. The carbohydrates are then converted into other organic materials by a variety of biosynthetic pathways.

Carbohydrates serve as sources (sugars) and stores of energy (starch and glycogen); they also form a major portion of the supporting tissue of plants (cellulose) and of some animals (chitin in crustacea and insects); they play a basic role as part of the nucleic acids DNA and RNA. Other carbohydrates are found as components of a variety of natural products, such as antibiotics, bacterial cell walls, blood group substances, glycolipids, and glycoproteins, the latter, due to their multifaceted carbohydrate-based recognition phenomena, forming the basis of glycobiology.

In the last decade, a large collection of books on carbohydrate chemistry and biochemistry have appeared, ranging from comparatively brief introductions [1–3] to more elaborate monographs [4–7] and multivolume comprehensive treatises [8], [9]. They are recommended as more profound sources of information.

2. Monosaccharides

The generic term 'monosaccharide' denotes a single sugar unit without glycosidic connection to other such units. Chemically, monosaccharides are either polyhydroxyaldehydes or *aldoses* (e.g., glucose) or polyhydroxyketones or *ketoses* (e.g., fructose), the ending 'ose' being the suffix to denote a sugar. Monosaccharides are classified according to the number of carbon atoms they contain, i.e., hexoses and ketohexoses (or hexuloses) of the general formula $C_6H_{12}O_6$ or pentoses and pentuloses ($C_5H_{10}O_5$). Subdivisions are made according to functional groups which may also be present, for example, aminohexoses ($C_6H_{13}O_5N$), deoxyhexoses ($C_6H_{12}O_5$), and hexuronic acids ($C_6H_{10}O_7$). Monosaccharides with fewer (trioses, tetroses) or more carbon atoms (heptoses, octoses, etc.) are rare.

D-*Glucose* (→ Glucose and Glucose-Containing Syrups, Chap. 2.) [*50-99-7*], also known as dextrose, blood sugar, or grape sugar ('*Traubenzucker*' in German), is a pentahydroxyhexanal, hence belonging to the class of aldohexoses (see Section 2.1). Glucose can be considered the parent compound of the monosaccharide family, because it is not only the most

Figure 1. Structural formula of aldohexoses, of which due to the four chiral centers (marked by ∗) 16 stereoisomers are possible

Figure 2. Configurational representations of the linear (acyclic) form of D-glucose: Traditional Fischer projection formula (top left) and its transformation into the more realistic dashed-wedged line depictions with the six-carbon chain in zigzag arrangement.

abundant monosaccharide in nature but also the one most extensively studied. It occurs as such in many fruits and plants, in concentrations of 0.08 – 0.1 % in human blood, and constitutes the basic building unit of starch, cellulose, and glycogen. Other ubiquitous aldohexoses are D-*mannose* [*3458-28-4*], occurring naturally mainly in polysaccharides ('mannans', e.g., from ivory nut) and D-*galactose* [*59-23-4*], a frequent constituent of oligosaccharides, notably lactose and raffinose, and of primary cell wall polysaccharides (pectins, galactans, arabinogalactans). A corresponding isomeric 2-ketohexose is D-*fructose* [*57-48-7*] (→ Fructose), the sweetest natural sugar, which occurs in many fruits and in honey, and, glycosidically linked, in sucrose and the polysac-

Figure 3. The D-aldose family tree (up to aldohexoses) in their acyclic forms: Common names and Fischer projection formulas, with secondary hydrogen atoms omitted for clarity.

charide inulin, a reserve carbohydrate for many plants (chicory, Jerusalem artichoke). Other important natural sugars are the aldopentose D-*ribose* [*50-69-1*], which constitutes a building block of the ribonucleic acids, L-*arabinose*, widely distributed in bacterial polysaccharides, gums and pectic materials, and D-*xylose* [*58-86-6*], of widespread occurrence in pentosans ('xylans') that accumulate as agricultural wastes (cottonseed hulls, corn cobs).

2.1. Structure and Configuration

D-Glucose, the most abundant monosaccharide, has the molecular formula $C_6H_{12}O_6$ as shown by elemental analysis and molecular mass determination. As evidenced from ensuing reactions (see below) this is consistent with a six-carbon, straight-chain pentahydroxyaldehyde of the following structural formula, an aldohexose in carbohydrate notation (Fig. 1).

This structure contains four asymmetric centers, thus $2^4 = 16$ stereoisomers exist, which can be grouped into eight pairs of enantiomers, and classified as D- and L-sugars. In the D-sugars, the highest numbered asymmetric hydroxyl group (C-5 in glucose) has the same configuration as the asymmetric center in D-glyceraldehyde and, likewise, all L-sugars are configurationally derived from L-glyceraldehyde. A convenient way

Figure 4. The D-ketohexose (or D-hexulose) family tree: Trivial names, systematic designation (in brackets) and Fischer projection formulas.
† Not regarded as being a sugar, due to absence of an asymmetric carbon atom.

to show configurational relationships was introduced by EMIL FISCHER in 1891 [10], [11], now termed Fischer projection formula (Fig. 2), as it – literally – projects tetrahedral space relationships into a plane. The resulting formulas are simple to write and easy to visualize, yet they require the setting up of conventions: The carbon chain of a sugar is oriented vertically and to the rear with the aldehyde group at the top; hydrogen atoms and hydroxyl groups at the asymmetric carbon atoms stand out in front. The resulting three-dimensional model is then imagined to be flattened and the groups are laid on the plane of the paper. If the lower-most asymmetric center (C-5 in glucose) has the OH group to the right, it is considered to have the D-configuration. FISCHER's decision to place the OH group of natural glucose to the right, hence D-glucose, was purely arbitrary, yet proved to be a fortunate one, since much later, in 1951, it was proven by special X-ray structural analysis [12] that he had made the right choice.

The D-aldose family tree is shown in Figure 3, comprising five of the most important monosaccharides, the aldopentoses D-ribose and D-xylose, and the hexoses D-glucose, D-mannose, and D-galactose, each having the hydroxyl group at the highest-numbered stereocenter (at the bottom) pointing to the right. Likewise, all L-aldoses are configurationally derived from L-glyceraldehyde, entailing a family tree with the lowest OH group to the left; the respective projection formulas being, in essence, mirror images to those in Figure 3.

A similar system is used to build up the series of ketohexoses or hexuloses, i.e., monosaccharides with a keto group at C-2, which therefore contain one asymmetric carbon atom less (Fig. 4).

2.2. Ring Forms of Sugars: Cyclic Hemiacetals

In the solid state and in solution monosaccharides exist in a cyclic hemiacetal form, ring closure corresponding to reaction between the aldehyde group and either the C-4-OH or C-5-OH. Cyclization involving *O*-4 results in a five-membered ring structurally related to furan and therefore designated as a *furanose*, whilst hemiacetal formation with *O*-5 gives rise to an essentially strain-free, hence sterically more favored, six-membered ring, a derivative of pyran, hence termed a *pyranose*. Either ring formation generates a new asymmetric carbon atom at C-1, the anomeric center, thereby giving rise to diastereomeric hemiacetals which are called and labeled α and β. For visualization of the cyclic hemiacetal forms of sugars, HAWORTH, in 1928 [13], introduced his projection formula, in which the rings are derived from the open-chain form and drawn as lying perpendicular to the paper with the ring oxygen away from the viewer. To facilitate this mode of viewing, the front part is usually accentuated by wedges as shown in Figure 5 for the β-anomers of pyranose and furanose forms of D-glucose. The projections devised by MILLS

in 1954 [14], corresponding to those customary for terpenes and steroids, are also very useful for revealing the stereochemistry of sugars in their cyclic hemiacetal forms: the ring is placed in the plane of the paper with solid or broken wedge-shaped lines to show the orientation of substituents, i.e., OH and CH_2OH groups.

Figure 5. Haworth and Mills projection formulas for the β-anomers of D-glucopyranose and D-glucofuranose (in the formula at the center and at the bottom, the carbon and C-hydrogen atoms are omitted for clarity).

2.3. Conformation of Pyranoses and Furanoses

The concepts of conformation are fundamental to a proper understanding of the structure-property relationships of carbohydrates, most notably of the regio- and stereoselectivities of their reactions. The conformational analysis of monosaccharides is based on the assumption that the geometry of the pyranose ring is essentially the same as that of cyclohexane and, analogously, that of furanoses the same as that of cyclopentane – a realistic view, since a ring oxygen causes only a slight change in molecular geometry. Hence, the rhombus-shaped Haworth formulas which imply a planar ring, and the equally flat dashed-wedged line configurational depictions by Mills (Fig. 5) are inadequate to represent the actual three-dimensional shape of the rings and the steric orientation of the ring substituents (OH and CH_2OH groups). For the six-membered pyranose ring a number of recognized conformers exist [15]: two chairs ($^1C_4$, $^4C_1$), six boats (e.g., $^{1,4}B$ and $B_{1,4}$ in Fig. 6), six skews and twelve half-chairs (e.g., $^oS_2$ and $^5H_4$ forms).

Figure 6. Conformational forms of pyranose rings: chair (C), boat (B), skew (S) and half-chair (H).
To designate each form, the ring atom numeral lying above the plane of reference appears as a superscript preceding the letter, those below the plane are written as subscripts and follow the letter.

Figure 7. Cyclic hemiacetal forms of D-glucose in configurational representation. In solution, these forms rapidly interconvert through the energetically unfavorable acyclic form; in water at 25 °C the two pyranoid forms are nearly exclusively adopted, the equilibrium mixture amounting to 62 % of the β-p and 38 % of the α-p anomers. From water, D-glucose crystallizes in the α-pyranose form.
The six-membered (pyranose) ring is denoted by the symbol p after the three-letter symbol for the monosaccharide (for example, Glc$p$), the five-membered (furanose) ring correspondingly is signated by an f (e.g., Glc$f$).

Although there are exceptions, most aldohexoses adopt the chair conformation that places the bulky hydroxymethyl group at the C-5 terminus in the equatorial position. Hence, β-D-hexopyranosides are predominantly in the $^4C_1$ chair conformation, since each of the alternative forms outlined in Figure 6, most notably the $^1C_4$ chair, are energetically less favored. For glucose, this preference means that, in the α-form, four of the five substituents are equatorial, and one is forced to lie axial; in the β-form, all substituents are equatorial (Fig. 7). This situation is unique for glucose; the other seven D-aldohexoses contain one or more axial substituents.

Figure 8. Forms of D-fructose in solution. In water, the major conformers are the β-pyranose (β-*p*, 73 % at 25 °C) and β-furanose (β-*f*, 20 %) forms [17]. On crystallization from water, D-fructose adopts the $^2C_5$ chair conformation in the crystal lattice as evidenced by X-ray analysis [16].

The hexulose counterpart to the conformational forms of D-glucose is the D-fructose isomerization scheme depicted in Figure 8. Whilst the crystalline product is the β-D-fructopyranose in the $^2C_5$ chair conformation as evidenced by X-ray analysis [16], on dissolution in water, equilibration is essentially instantaneous to yield a mixture mainly containing the β-*p*-form (73 % at 25 °C, the only sweet one in fact), together with the β-*f*- (20 %), α-*f*- (5 %) and α-*p*-forms (2 %) [17]. The acyclic form through which equilibration occurs is present to a minute extent only.

The principal conformations of the furanose ring are the *envelope* (*E*) – one atom lying above or below a plane formed by the other four ring atoms – or the *twist* (*T*) arrangement, in which three ring atoms are in a plane and the other two above and below, respectively. As energy differences between the various *E* and *T* conformations are small, the form actually adopted depends on the type of ring substitution (hexoses, hexuloses, pentoses), their configuration, their solvation and the type of intra- or intermolecular hydrogen bonding present. Accordingly, the exact conformation of an individual furanose is usually not known – except for the crystalline state when an X-ray structural analysis is available. Thus, the planar Haworth and Mills projection formulas are the preferred way of drawing furanose forms (Fig. 9).

Figure 9. The envelope conformation (top left) is the ^3E form as defined by the C-3 atom lying above the plane formed by the other ring atoms. The defined plane for the twist form (top right) is the triangle given by C-1, C-4, and O-4, entailing the conformational description $^3T_2$. In aprotic solvents (dimethylsulfoxide) D-fructose populates the E_2 envelope conformation to a substantial extent [17], whilst in crystalline sucrose, the β-D-fructofuranose portion adopts the $^4T_3$ twist form [18], [19] (bottom entries).

2.4. Structural Variations of Monosaccharides

Sugars may possess functionalities other than hydroxyl groups. Amino sugars are aldoses, which have a hydroxyl group replaced by an

amino functionality, e.g., D-*glucosamine* (2-amino-2-deoxy-D-glucose), which is one of the most abundant. In its *N*-acetylated form (*N*-acetyl-D-glucosamine), it is a constituent of the polysaccharide chitin (→ Chitin and Chitosan), that forms the hard shells of crustaceans and other anthropods, but also appears in mammalian glycoproteins and links the sugar chain to the protein. Monosaccharides lacking a hydroxyl group at the terminal C-6, i.e., 6-deoxy-sugars, are likewise of wide occurrence, for example, L-*rhamnose* (6-deoxy-D-mannose) is found in plant and bacterial polysaccharides whereas L-*fucose* (6-deoxy-D-galactose) is present in combined form in animals, plants, and microorganisms. 2-Deoxy-D-*erythro*-pentose (2-deoxy-D-ribose) is the exceedingly important sugar component of DNA, various mono-, di- and trideoxy sugars are constituents of many antibiotics, bacterial polysaccharides, and cardiac glycosides.

The uronic acids are aldoses that contain a carboxylic acid chain terminating function, and occur in nature as important constituents of many polysaccharides. The D-gluco compound, D-*glucuronic acid*, was first isolated from urine (hence the name), in which it occurs as glycosides and glycosyl esters of toxic substances that the body detoxifies in this way.

(L-Rha*p*)

D-Glucuronic acid
(D-GlcA*p*)

D-Apiose
3-C-hydroxymethyl-D-*glycero*-tetrose (D-Api*f*)

Branched-chain sugars, i.e., saccharides with a non-linear carbon chain, are comparatively uncommon, the more widely occurring being D-*apiose* (3-C-hydroxymethyl-D-*glycero*-tetrose), richly present in polysaccharides of parsley and duckweed [20], and D-*hamamelose* (2-C-hydroxymethyl-D-ribose), a component of the bark of witchhazel [21].

3. Oligosaccharides

Oligosaccharides are compounds in which monosaccharide units are joined by glycosidic linkages, i.e., simple polymers containing between two and ten monosaccharide residues. Accordingly, there are disaccharides – a disaccharide composed of two hexopyranoses can have 5120 distinguishable isomeric forms – trisaccharides, tetrasaccharides, etc. They may be further subdivided into homo- (consisting of only one type of sugar) and hetero-oligosaccharides, and into those that are reducing (presence of a free hemiacetal group) or non-reducing. A comprehensive listing of the di-, tri-, and higher oligosaccharides known by 1990 is available [22].

3.1. Common Disaccharides

Sucrose, affectionately called "the royal carbohydrate" [23], is a non-reducing disaccharide because its component sugars, D-glucose and D-fructose, are glycosidically linked through their anomeric carbon atoms: Sucrose is a β-D-fructofuranosyl α-D-glucopyranoside (see Fig. 10). It is widely distributed throughout the plant kingdom, is the main carbohydrate reserve and energy source and an indispensable dietary material for humans (→ Sugar). For centuries, sucrose has been the world's most plentiful produced organic compound of low molecular mass, the present annual production from sugar-cane and sugar beet being an impressive 130×10^6 t [24].

α,α-Trehalose, a non-reducing D-glucosyl D-glucoside occurs extensively in the lower species of the plant kingdom (fungi, young mushrooms, yeasts, lichens, and algae). In baker's yeast it accounts for as much as 15 % of the dry mass, in the metabolic cycle of insects it circulates like glucose does in the mammalian

Figure 10. Common structural representations of sucrose (top entries), the molecular geometry realized in the crystal featuring two intramolecular hydrogen bonds between the glucose and fructose portion [18], [19] (bottom left), and the sterically similar disposition of the two sugar units towards each other in aqueous solution form, caused by hydrogen bonding through a 'water bridge' [25]. The bottom entries show the solvent-accessible surfaces (dotted areas) of the crystal form (left) and the form adopted in water [25] (right), clearly demonstrating that sucrose has an unusually compact overall shape, more so than any other disaccharide.

cycle. Similarly nonreducing, due to being a galactosylated sucrose, is the trisaccharide *raffinose*, distributed almost as widely in the plant kingdom as sucrose, yet in lower concentration (e.g., less than 0.05 % in sugar beets).

There are only very few naturally occurring oligosaccharides with a free anomeric hydroxyl group, which therefore possess reducing properties. The most important example is *lactose* (milk sugar, → Lactose and Derivatives), an ingredient of the milk of mammals (up to 5 % in cows). As it is produced on an industrial scale from whey, it represents the only large-scale

available sugar derived from animal rather than plant sources. Uses include human food, pharmaceuticals, and animal feeds. The reducing gluco-disaccharides *cellobiose* and *maltose* (malt sugar) are chemical or enzymatic hydrolysis products of the polysaccharides cellulose and starch, respectively, and, hence are not regarded as native oligosaccharides.

Isomaltulose (palatinose, → Sugar Alcohols, Chap. 5.1.) and *lactulose*, both produced in fairly large amounts from sucrose and lactose, respectively, are 6-*O*-glucosyl- and 4-*O*-galactosyl-fructoses. The sucrose → isomaltulose transformation, industrially realized at a 40 000 t/a-scale [26], is effected by a *Protaminobacter rubrum*-induced glucosyl shift from the anomeric fructosyl oxygen to its *O*-6, taking place in mostly intramolecular fashion via a closed-shell intermediate [27], whilst the generation of lactulose from lactose, presently running at a 12 000 t/a level, comprises a base-promoted C-1 → C-2 carbonyl shift. Most of the isomaltulose produced is subsequently hydrogenated to isomalt (→ Sugar Alcohols, Chap. 5.2.), a low-calorie sweetener with the same taste profile as sucrose, lactulose (→ Lactose and Derivatives, Chap. 2.1.) has medical and pharmaceutical applications, mainly for treating intestinal disorders.

Other Heterooligosaccharides. Heterooligosaccharides of considerably higher complexity occur in large variety in plants, animals and microorganisms where they are covalently bound to proteins ('glycoproteins') and lipids ('glycolipids') or other hydrophobic entities, and, as such, are implemented in a range of key biological processes: cell-cell recognition, fertilization, embryogenesis, neuronal development, hormone activities, the proliferation of cells and their organization into specific tissues, viral and bacterial infection and tumor cell metastasis [28–30]. Red blood cells, for example, carry carbohydrate antigens which determine blood group types in humans: type A people have the tetrasaccharide in Figure 11 with R = NHAc (i.e., a GalNAc residue) as a key antigen linked by lipid components to the surfaces of red blood cells; in type B blood, the tetrasaccharide determinant is exceedingly similar – formal replacement of NHAc by OH, i.e., GalNAc by

Gal – yet on mixing with type A blood leads to clumping and precipitation [31].

Figure 11. Human blood groups determinants: Differentiation between type A (R = NHAc) and B (R = OH) is effected by relatively simple changes within a branched tetrasaccharide linked to lipid components on the surface of red blood cells.

All *N*-glycoproteins (*N*-glycans) share the peptide-linked pentasaccharide fragment in Figure 12, consisting of three mannose units in a branched arrangement and two GlcNAc residues, of which the terminal one is *N*-glycosidically linked to an asparagine moiety of the protein. Branching out from this uniform core region are monosaccharides and oligosaccharide chains of high structural diversity leading to multiple types of branched and unbranched glycoproteins [32].

3.2. Cyclodextrins (→ Cyclodextrins)

Although discovered more than 100 years ago, the cyclic glucooligosaccharides termed cyclodextrins (based on dextrose, which is an old name for glucose) remained laboratory curiosities until the 1970s when they started to be used commercially [33]. Their large-scale production is based upon the degradation of starch by enzymes elaborated by *Bacillus macerans* ('CGTases'), involving excision and reconnection of single turns from the helical α-(1→4)-glucan (amylose) chain (cf. Fig. 13) to provide cyclic α-(1→4)-linked glucooligosaccharides with six, seven and eight glucose units. They are named α-, β- and γ-cyclodextrin, respectively.

Cyclodextrins are truncated cones with well-defined cavities. All secondary hydroxyl groups are located at the wider rim of the cone leaving the primary CH_2OH groups to protrude from the narrower opening. The respective cavities, as exemplified by that of α-cyclodextrin with its six glucose units (Fig. 14, [34], [35]), are distinctly hydrophobic in character, and show an amazing propensity to form stable complexes with a large variety of equally hydrophobic, sterically fitting guest molecules by incorporating them into their cavities [33], [34], changing the physical and chemical properties of the included guest. The features and properties of the resulting cyclodextrin inclusion compounds has led to the exploitation of cyclodextrins for a wide variety of purposes: as drug carriers [36], [37], as stationary phases for the separation of enantiomers [38], [39], as building blocks for supramolecular structures [40], and as enzyme models [41].

4. Polysaccharides

The bulk of the annually renewable carbohydrate-biomass are polysaccharides (glycans), such as cellulose, hemicelluloses, chitin, starch, and inulin. Invariably composed of monosaccharide units, they have high molecular masses and, hence, differ significantly in their physical properties. The majority of naturally occurring polysaccharides contain 80 – 100 units, with a few though made up of considerably more.

Cellulose (→ Cellulose) [*9004-34-6*] is an unbranched glucan composed of β-(1→4)-linked D-glucopyranosyl units (see Fig. 15) with an average molecular mass equivalent to about 5000 units. It is the most abundant organic material found in the plant kingdom, forming the principal constituent of the cell walls of higher plants and providing them with their structural strength. Cotton wool is almost pure cellulose, but in wood, the other chief source of the polymer, cellulose is found in close association with other polysaccharides (mainly hemicelluloses) and lignin. X-ray analysis and electron microscopy indicate that these long chains lie side by side in bundles, held together by a multiplicity of hydrogen bonds between the numerous neighboring OH groups. These bundles are twisted to-

gether to form rope-like structures, which themselves are grouped to form the fibers that can be seen. In wood (→ Wood, Chap. 1.) these cellulose "ropes" are embedded in lignin to give a structure that has been likened to reinforced concrete.

Chitin (→ Chitin and Chitosan) is a polysaccharide composed of β-(1→4)-linked 2-acetamido-2-deoxy-D-glucopyranosyl residues (cf. Fig. 15), of which about one out of every six is not acetylated. Chitin is the major organic component of the exoskeleton (shells) of insects, crabs, lobsters, etc. and, hence, an abundant byproduct of the fishing industries. *Chitosan*, a related water-soluble polysaccharide in which the vast majority of residues is not acetylated (i.e., a β-(1→4)-linked chain of 2-amino-2-deoxy-D-glucose residues), can be obtained from chitin by deacetylation in concentrated sodium hydroxide solution.

Starches (→ Starch). The principal food-reserve polysaccharides in the plant kingdom are starches. They form the major source of carbohydrates in the human diet and are therefore of great economic importance, being isolated on an industrial scale from many sources. The two components, amylose and amylopectin, vary in relative amount among the different sources from less than 2 % of amylose in waxy maize to about 80 % of amylose in amylomaize (both

Figure 16. Sketch illustration of a left-handed, single stranded helix of V_H-amylose (top) and more detailed representation of its molecular geometry based on X-ray diffraction data [42] and calculation of the solvent-accessible contact surfaces [43], indicated by dots with ball-and-stick models superimposed.
Center: The channel generated by the helical arrangement of the α-D-glucose residues, of dimensions corresponding to those of the cavity of α-cyclodextrin, is clearly apparent. The outside surface area of V_H-type amylose is uniformly hydrophilic (in conformity with its solubility in water) whereas the center channel is as distinctly hydrophobic – predestined to incorporate equally hydrophobic guests such as iodine or fatty acids [43].
Bottom: A linear polyiodide chain embedded into the channel, corresponding to the intense blue starch-iodine complex [43].

corn starches), but the majority of starches contain between 15 and 35 % amylose.

Amylose [*9005-82-7*] is made up of long chains, each containing 100 or more α-(1→4)-linked glucopyranosyl units which due to the kink in every α-glycosidic linkage tend to coil to helical segments with six glucose units forming one turn (see sketch in Fig. 13). Amylose is the fraction of starch that gives the intense blue color with iodine, which has its cause in the trapping of iodine molecules within the hydrophobic channel of the helical segments of the polysaccharide (Fig. 16).

Amylopectin [*9037-22-3*] is also an α-(1→4)-glucan, yet there is a branch point via *O*-6 about every 25 units. The molecular size of amylopectin is of the order of 10^6 D-glucose residues, making it one of the largest naturally occuring molecules. The secondary structure is characterized by a several hundred linear chains of about 20 – 25 glucose units each, which are connected in a variety of arrangements to give

Figure 17. Schematic representation of a section of amylopectin with an $\alpha(1\rightarrow6)$-branch of a helical chain of $\alpha(1\rightarrow4)$-glucopyranosyl residues (left), with the tassel-on-string model of its higher level structure (ϕ = reducing end)

clusters for which the tassel-on-a-string model (see Fig. 17) has been proposed. With iodine, amylopectin produces only a dull-red color, indicating that the short linear chain portions cannot coil effectively to the helices required for formation of inclusion complexes.

Figure 18. Nystose fragment of inulin, showing subfragments corresponding to sucrose, inulobiose and 1-kestose. Commercial inulins, e.g., those isolated from chicory, have a degree of polymerization far below that found in other polysaccharides, their molecular sizes ranging from around 5 to 30 units [43].

Dextrans (→ Dextran) are linear water-soluble α-(1→6)-glucans with only occasional branches via *O*-2, *O*-3 or *O*-4. They are generated from sucrose by a large number of organisms, of which *Leuconostoc mesenteroides* is used to produce the slightly branched commercial dextran, used clinically as a plasma volume expander.

Inulin is a polysaccharide composed of $\beta(1\rightarrow2)$-linked D-fructofuranose units with varying chain length of about 15 – 30 units. It is present to the extent of 30 % or more in various plants such as dahlia or Jerusalem artichoke where it replaces starch either partially or completely as the food storage carbohydrate [44], [45]. The structure of inulin is unique in leaving no 'reducing end', as this is glycosidically blocked by an α-D-glucopyranose residue – a sucrose unit in fact (Fig. 18).

Other Polysaccharides (→ Polysaccharides). A plethora of other homo- and heteropolysaccharides are abound in nature, most notably D-*xylans* (hemicelluloses with linear chains of β-(1→4)-D-xylopyranosyl units), *pectins* (principal constituent D-galacturonic acid), plant gums (building blocks D-galactose, L-arabinose, L-rhamnose) and various algal and microbial polysaccharides with, in part, unusual sugar units: L-guluronic and D-mannuronic acids in alginates, glucuronic acid and pyruvate acetals in *agar*, sulfated galactosyl residues in

carrageenans, or ribitol phosphates in *teichoic acids*. Excellent accounts on this subject have been given [46], [47].

5. Nomenclature

According to common practice, trivial names are used for monosaccharides and for many naturally occurring oligosaccharides. With the development of carbohydrate chemistry, however, and ever-increasing numbers of newly defined compounds, it has become necessary to introduce a semisystematic nomenclature which has been approved by the joint commission of IUPAC (International Union of Pure and Applied Chemistry) and IUB (International Union of Biochemistry) [48]. This nomenclature is based on the classical names for monosaccharides which appear, written in italics, as a "configurational prefix". For example, D-*xylo*, L-*arabino*, D-*gluco* refer to the distribution of asymmetric carbon atoms along a carbon chain of any length, designating the configuration of the corresponding monosaccharide.

Monosaccharides with an aldehydic carbonyl or potential aldehydic carbonyl group are called aldoses; those with a ketonic or potential ketonic carbonyl group, ketoses, with the chain length given by the root, such as pentose, hexose, or heptose and pentulose, hexulose, etc. In ketoses the position of the keto group is indicated by the position number. D-Fructose is systematically named D-*arabino*-2-hexulose.

Replacement of a hydroxyl group by hydrogen is indicated by the prefix deoxy, e.g., L-rhamnose is a 6-deoxy-L-aldohexose of *manno*-configuration. Replacement of a hydroxyl group by any other substituent is formally regarded as going via the deoxysugar. Thus a sugar with an amino group instead of OH is called an amino-deoxysugar. Formation of ether groups, most commonly methyl, is indicated by adding '*O*-methyl-' to the front of the name preceded by the number of the carbon atom whose hydroxyl group has been etherified. Esters, for example, acetates are shown by adding either '*O*-acetyl-' before the name or 'acetate' after it, in each case again preceding it with the appropriate carbon number.

The ring size is indicated by a suffix: pyranose for six-membered rings, furanose for five-membered rings, and pyranulose for six-membered ketose rings. The six-membered cyclic hemiacetal of D-fructose is named D-*arabino*-2-hexopyranulose. The symbol α or β for the anomeric configuration is always written together with the configurational symbol D or L (α-D, β-D, α-L, β-L).

Names of oligosaccharides are formed by combining the monosaccharide names, usually the trivial names. The nonreducing disaccharide sucrose is β-D-fructofuranosyl α-D-glucopyranoside. The endings "yl" and "ide" describe the fructose part as the aglycone and the glucose part as the glycone in this "glycoside". It is thus clearly indicated that both sugars are glycosidically linked by their anomeric hydroxyl groups. In reducing oligosaccharides the reducing monosaccharide is the root, and all attached monosaccharide units are named as substituents. The disaccharide lactose is therefore named β-D-galactopyranosyl-(1$\rightarrow$4)-D-glucopyranose. Position numbers and arrows indicate a β-configurated glycosidic bond between the anomeric hydroxyl group (carbon atom 1) of D-galactose (glyconic part) and the hydroxyl group at carbon atom 4 of D-glucose (aglyconic part).

For description of more complex oligosaccharides an abbreviation system has come into use - as for oligopeptides and oligonucleotides - that is unambiguous and practical: each monosaccharide is abbreviated by a three-letter symbol, comprising the first three letters of its trivial name, i.e.:

Glucose	Glc	Xylose	Xyl
Fructose	Fru	Arabinose	Ara
Galactose	Gal	Ribose	Rib
Mannose	Man	Deoxyribose	dRib
Fucose	Fuc	Glucosamine	GlcN
Rhamnose	Rha	*N*-Acetylglucosamine	GlcNAc

The anomeric configuration and D- or L-affiliation is written before the three-letter acronym, the ring size (*p* for pyranose, *f* for furanose) is added to the end, followed by the intersaccharidic linkage position in the case of oligosaccharides. Sucrose (Fig. 10), accordingly, is β-D-Fru*f*-(2$\rightarrow$1)-α-D-Glc*p*, lactose β-D-Gal*p*-(1$\rightarrow$4)-D-Glc*p*.

6. General Reactions

6.1. Hydrolysis

The hydrolysis of disaccharides such as sucrose and lactose, or polysaccharides like starch and cellulosic materials to their free component sugars is of great importance in the food and fermentation industries. It can be effected by enzymes called glycosidases or by acid treatment.

Enzymatic hydrolysis proceeds with high specificity towards both the sugar and the configuration at the anomeric center. Maltase, an α-D-glucosidase obtainable from barley malt, catalyses the hydrolysis of α-linked di-, oligo- and polysaccharides (sucrose, maltose, starch, dextrans), whereas the almond emulsin-derived enzyme is a β-glucosidase cleaving only β-linked glycosides.

Acid-induced hydrolysis of glycosides requires comparatively harsh conditions, standards being 1 M sulfuric acid at 100 °C for 4 h for hexose-containing polysaccharides and 0.25 M H_2SO_4 at 70 °C for pentosans. Partial degradation of the resulting monosaccharides can usually not be avoided whatever conditions are used [49], [50]. Thus, aside from enzymatic hydrolysis, acid hydrolysis of *starch* is industrially performed on a 10^6 t/a basis, the resulting D-glucose being used in liquid form (corn syrup) as a sweetener (→ Glucose- and Glucose-Containing Syrups, Chap. 4.). Another significant industrial product, in fact the only large-volume organic chemical prepared from carbohydrate sources (~ 200 000 t/a), is furfural (2-furaldehyde) [51], [52]. The technical process involves exposure of agricultural or forestry wastes to aqueous acid and fairly high temperatures, the *pentosans* first being hydrolyzed to pentoses, then undergoing cyclodehydration (→ Furan and Derivatives, Chap. 3.).

Similarly accessible by acid-induced elimination of three moles of water from *fructose* or *inulin hydrolysates* is 5-hydroxymethylfurfural (HMF) [26], [53].

When using nonaqueous conditions, e.g., DMSO as the solvent and a strongly acidic resin, the fructose part of disaccharides such as isomaltulose can similarly be converted into the respective, glucosylated HMF-derivative (GMF) without cleaving the acid-sensitive glycosidic linkage [54].

The trisaccharide *raffinose*, a storage carbohydrate in many plants can be cleaved enzymatically with α-galactosidase into sucrose and galactose. This reaction is used in the beet sugar industry to increase the yield of sucrose, as well as to improve the digestibility of food from leguminous plants. Raffinose can also be fermented by baker's yeast to form melibiose (α-D-Gal*p*-(1→6)-D-Glc*p*).

6.2. Isomerization

Under basic conditions aldoses isomerize to their C-2 epimers and the corresponding ketoses. Specific conditions may be applied for the preparation of particular products. In 0.035 % aqueous sodium hydroxide at 35 °C for 100 h, for example, either of the three following sugars is

converted into an equilibrium mixture containing D-glucose (57 %), D-fructose (28 %), and D-mannose (3 %). This interconversion is known as the *Lobry de Bruyn – van Ekenstein rearrangement* [55], which occurs by enolization of either sugar to the 1,2-enediolate – the mechanism being best visualized in the Fischer projection formulae (Fig. 19). In favorable cases alkali-promoted stereoisomerizations can be of preparative use, especially when the starting sugar is relatively abundant and when structural features minimize competing reactions. Thus lactulose can be satisfactorily made by epimerization of lactose (→ Lactose and Derivatives, Chap. 2.1.2.), or maltulose from maltose [56], [57], using either sodium hydroxide alone or with borate or aluminate as coreagents.

Figure 19. Lobry de Bruyn – van Ekenstein rearrangement

Alternatively, C-2-epimerization without ketose involvement can be induced by use of molybdate under mildly acidic conditions. This remarkable transformation (*Bilik reaction*) [58] involves a C-1 / C-2 interchange within the carbon skeleton.

6.3. Decomposition

Exposure of carbohydrates to high temperatures leads to decomposition (dehydration) with darkening (caramelization). This can be used to produce the caramel color, e.g., the color of cola beverages. Thermal decomposition in the presence of amino acids (*Maillard reaction* [59]) is responsible for many color- and flavor-forming reactions, such as in baking of bread and roasting of meat or coffee. The highly complex Maillard reaction, elicited during cooking or the preservation of food, involves condensations, Amadori-type rearrangements of glycosylamine intermediates, and degradations. The dark-colored products formed are responsible for the nonenzymic browning observed with various foodstuffs.

7. Reactions at the Carbonyl Group

In solution, reducing sugars establish an equilibrium between their pyranoid and furanoid hemiacetal forms via the open-chain carbonyl species. Although the latter is present only to a very minor extent, equilibration between the different forms is fast, so that reducing sugars undergo the typical carbonyl reactions with *O*-, *N*-, *S*-, and *C*-nucleophiles.

7.1. Glycosides

With alcohols in the presence of acid catalysts reducing sugars give the respective full acetals, called glycosides (Fischer glycosidation) [60]. Depending on the distribution of furanoid and pyranoid tautomeric forms in the reaction mixture, not only glycosides with different ring sizes, i.e., glycopyranosides and glycofuranosides, can result, but also the α- and β-anomers of each. Thus, when D-glucose is heated with methanol in the presence of anhydrous hydrogen chloride, pure crystalline methyl α-D-glucopyranoside can be isolated in 90 % yield, whilst the same reaction with D-galactose yields a mixture of the two furanoid and pyranoid methyl galactosides, from which the methyl α-D-galactopyranoside can be obtained in crystalline form in 41 % yield only.

Although the Fischer glycosidation presents one of the easiest means for preparing glycosides, synthesis of more complex members of this series, particularly the construction of the biologically important heterooligosaccharides widely distributed in nature, requires the use of more sophisticated methodologies. These preparative techniques generally involve the

coupling of suitably OH-group protected glycosyl donors (i.e., glycosides with an anomeric leaving group) with an alcohol component – usually a mono-, di-, or oligosaccharide in which the hydroxyls carry protecting groups [61] except for the one to be glycosylated ('the glycosyl acceptor'). Effective glycosyl donors, derived from D-glucose, are listed in Table 1. They represent the presently most suitable donors for achieving glycosidic bond-forming reactions with high stereocontrol: glycosyl chlorides and bromides [62], 2-oxoglycosyl bromides [63], [64], anomeric phosphates [65] and trichloracetimidates [66], thioglycosides [67], glycosyl sulfoxides [68], and 1,2-anhydrides [69], some of these methodologies being amenable to combinatorial and solid phase synthesis [70].

Table 1. Established glycosyl donors for the stereoselective synthesis of oligosaccharides

For further details on this subject, presently under intense further exploration, some recent general treatments [29], [71–73] are recommended.

7.2. Thioacetals and Thioglycosides

Sugars react rapidly with alkanethiols in the presence of acid catalysts at room temperature to give acyclic dialkyl dithioacetals as the main products [74], and therefore the reaction is markedly different from the Fischer glycosidation. These open-chain compounds can be used to prepare monosaccharide derivatives with a free carbonyl group, such as 2,3,4,5,6-penta-*O*-acetyl-D-glucose:

1-Thioglycosides, established glycosyl donors in oligosaccharide syntheses (upon activation with methyl trifluoromethanesulfonate or other promoters), have to be prepared indirectly, e.g., from peracylated pyranoses (or their 1-halides) by exposure to thiols in the presence of BF_3 etherate or zinc chloride:

7.3. Glycosylamines, Hydrazones, and Osazones

Aldoses condense with ammonia and with primary and secondary amines upon loss of water – reactions that are analogous to the Fischer glycosidation. The initial condensation products appear to be the open-chain aldimines which then cyclize to the *glycosylamines* – also called *N*-glycosides, Thereby, the pyranose forms are preferentially adopted as these are thermodynamically more stable. Accordingly, D-glucose reacts with aniline in methanol to the α- and β-*N*-glucopyranosides:

Acids also catalyze a transformation called the *Amadori rearrangement* [75] which often accompanies attempts to prepare glycosylamines from aldoses and amines. This reaction is related to the *Lobry de Bruyn-van Ekenstein reaction* of aldoses involving the rearrangement of *N*-alkylamino-D-glucopyranosides into 1-alkylamino-1-deoxy-D-fructoses (Fig. 20).

Figure 20. Amadori rearrangement of glycosyl amines induced by acid catalysis: D-Glucopyranosylamine is converted into 1-alkylamino-D-fructose [74]

Glycosylamine derivatives are probably involved in the complex Maillard reaction [59], whereby sugars, amines, and amino acids (proteins) condense, rearrange, and degrade during cooking or the preservation of food. Hydrazones and osazones result when aldoses or ketoses are reacted with hydrazine or arylhydrazines, the product depending on the conditions used [76]. With hydrazine acetate in highly acidic medium in the cold, hydrazones are formed, which initially adopt the acyclic structure, but tautomerize in aqueous solution to the cyclic glycosylhydrazine forms. However, when free sugars are treated with an excess of phenylhydrazine, the reaction proceeds further to give – in a formal oxidation of the vicinal 2-OH – the highly crystalline, water-insoluble phenylosazones which contain two phenylhydrazine residues per molecule, with a third phenylhydrazine molecule being converted into aniline and ammonia. As C-2 of a sugar is involved in this process, D-glucose, D-mannose, and D-fructose yield the same product:

D-Glucosazone

This result played a fundamental role in Emil Fischer's elucidation of the configurational interrelationships of the sugars, eventually leading [10], [11] to the sugar family trees depicted in Figures 3 and 4.

7.4. Chain Extension

The carbonyl group offers excellent opportunities for extension of the sugar chains and the formation of 'higher' sugars. However, only a few carbon nucleophiles can be applied directly to the free sugars, i.e., without protection of the OH groups. The classical methods comprise the addition of cyanide ion (*Kiliani – Fischer extension*) [77] and of nitromethane under suitable alkaline conditions [78]. In either case, the cyano and nitromethylene group newly introduced can be converted into an aldehyde functionality by hydrolysis of the diastereomeric cyanohydrins to aldonic acids, lactonization and subsequent reduction, or by applying the *Nef reaction* to the nitroalditols, thus providing methods for ascent of the sugar series. For example, the rare sugar D-allose can be readily prepared from D-ribose [79] (Fig. 21), whereas the nitromethane addition approach allows the acquisition of the equally scarce hexoses L-glucose and L-mannose from L-arabinose [80] (Fig. 22).

Figure 21. The Kiliani – Fischer cyanohydrin synthesis with D-ribose: the approximate 1:1 mixture of the 2-epimeric D-*allo*- and D-*altro*-cyanohydrins can be separated at the aldonic acid stage, subsequent reduction of the D-allonic acid in the form of its 1,4-lactone then providing D-allose (34 % overall yield)

Figure 22. Nitromethane addition to L-arabinose in alkaline medium generates a mixture of the 2-epimeric L-nitroalditols (of L-*gluco* and L-*manno* configuration) which upon separation are subjected to the Nef reaction [78]

A special case of chain extension by nitromethane is the cyclization of sugar-derived dialdehydes – readily and quantitatively obtained from anomerically blocked glycopyranosides or furanosides by periodate oxidation – to give 3-nitrosugars [81], [82]. As exemplified for methyl β-D-glucopyranoside (Fig. 23), a mixture of 3-nitrohexosides is primarily obtained from which the major product, the D-*gluco* isomer crystallizes. Subsequent catalytic hydrogenation then provides the 3-amino-3-deoxy-D-glucoside [83].

Figure 23. Conversion of methyl β-D-glucoside into its 3-amino-3-deoxy-derivative via the dialdehyde-nitromethane cyclization approach [81]

This nitromethane cyclization sequence can be extended to nitroalkanes, e.g., nitroethane or even nitroacetate [84], thus providing a ready access – upon hydrogenation of the nitro group – to 3-methyl- or 3–carboxy-branched 3-aminosugars.

7.5. Chain Degradation

The removal of a terminal carbon atom from a sugar or sugar derivative to leave an aldehyde group is realizable in a variety of ways but the yields are often poor. The most practical approach involves conversion of an aldose to the corresponding dialkyl dithioacetal (mercaptal) by reaction with an alkanethiol, then oxidation to the bis-sulfone with a peracid. Treatment of the bis-sulfone with dilute ammonia causes expulsion of the stabilized bis(ethylsulfonyl)methyl carbanion and gives the aldose with one carbon atom less. This three-step protocol smoothly converts D-glucose, for example, into D-arabinose [85]:

7.6. Reductions to Alditols

Aldoses and ketoses can readily be reduced to alditols (Table 2) with the generation of a new alcoholic group from the carbonyl functions, their names being derived from the respective aldose by replacing the 'ose' suffix with 'itol'. Thus, reduction of D-glucose gives D-glucitol. Originally, sodium amalgam was the reducing agent most commonly used for these reductions, but now it has been superseded by others, particularly sodium borohydride in aqueous solution, or for alkali-sensitive sugars, by $NaBH_3CN$ in acetic acid. High pressure hydrogenation of aldoses and ketoses over rare metal catalysts, especially nickel is used for the commercial preparation of alditols (→ Sugar Alcohols).

Table 2. Low-caloric, non-cariogenic sugar alcohol sweeteners, obtained by catalytic hydrogenation of the parent aldoses. Recommended nomenclature [48] for sorbitol is D-glucitol (hence D-Glc-ol). Being a *meso* compound, xylitol requires no D- or L-prefix .

d-Glucitol [*50-70-4*] (→ Sugar Alcohols, Chap. 3.), common name sorbitol, produced at a level of 900 000 t/a worldwide, has a sweet taste and is used in foods for diabetics [86], [87]. It is also the synthetic precursor for ascorbic acid (vitamin C), with about 20 % of the annual production sorbitol going to this use. Sorbitol is used as a humectant in cosmetic and pharmaceutical formulations and in foods. It is also applied as an alcoholic component in the preparation of rigid polyurethane foams. Fatty acid esters of monoanhydrosorbitol (1,4-sorbitan) are widely used as emulsifiers and non-ionic surfactants. The mono- and dinitrate esters of 1,4 : 3,6-dianhydrosorbitol (isosorbide [*652-67-5*]) are coronary vasodilators.

d-Mannitol [*87-78-5*] (→ Sugar Alcohols, Chap. 4.), is prepared by hydrogenation of the fructose portion of invert sugar [86], [88], which yields a mixture of mannitol and sorbitol. In contrast to sorbitol, mannitol is not hygroscopic; world production in 2000 was approximately 30 000 t. Mannitol is used in the manufacture of dry electrolytic condensers and synthetic resins; in the pharmaceutical industry as a diluent for solids and liquids and in the preparation of the vasodilator mannitol hexanitrate; in the food industry as an anticaking and free-flow agent, and as a lubricant, stabilizer, and nutritive sweetener.

Other sugar alcohols mostly used as sweeteners, are *xylitol*, obtained by catalytic hydrogenation of D-xylose, which in turn is acquired from wood xylans or maize cobs by acid hydrolysis, and a series of disaccharide alcohols, each manufactured analogously from the respective parent disaccharide: *maltitol* (from partially hydrolyzed starch syrup; Lycasin [88] contains a high proportion thereof), *lactitol* and, most notably, *isomalt*, which due to its mild, pleasant sweetness, ready crystallizability and excellent thermal stability appears presently the most prevailing. Isomalt, also called "Palatinit", consists of an approximate 1:1 mixture of α-D-glucosyl-(1→6)-D-sorbitol and α-D-glucosyl-(1→1)-D-mannitol (see Table 2). The latter forms a dihydrate, the two water molecules being attached to the mannitol portion in a hydrogen-bonded water bridge [89]. Isomalt is produced from sucrose through *Protaminobacter rubrum*-induced

isomerization to isomaltulose ('palatinose') and subsequent catalytic high-pressure hydrogenation (→ Sugar Alcohols, Chap. 5.2.).

7.7. Oxidation

Controlled stoichiometric oxidations of carbohydrates to yield glyconic acids or their derivatives are limited to aldoses. Such oxidations can be carried out almost quantitatively either enzymatically by dehydrogenases or oxidases or chemically with bromine or iodine in buffered solution. Under these conditions, D-glucose – through its pyranose form prevailing in solution – is directly converted into the 1,5-lactone of D-gluconic acid (i.e., the internal ester rather than the free acid), which on addition of base is converted to the salt (in open-chain form). However, by crystallization from aqueous solution it is possible to obtain the free acid or the 1,4-lactone. For different aldonic acids the amounts of each form present at equilibrium vary with structure and with pH of the solution, in contrast to the free sugars, the five-membered ring lactones are relatively favored.

Strong nitric acid appears to be one of the few oxidants which is able to also oxidize the terminal primary hydroxyl group of aldoses but leave the secondary hydroxyl groups unchanged. D-Glucose treated with this reagent gives D-*glucaric acid* [90], its name being derived by replacing the ending 'ose' in the sugar by 'aric acid'. Aldaric acids can form mono- or dilactones, in the case of D-glucaric acid, the well crystallizing form is the furanoid 1,4-lactone:

Under the influence of very strong oxidizing agents such as potassium dichromate or permanganate, sugars suffer oxidative degradation. Hence, these agents are of no preparative use.

8. Reactions at the Hydroxyl Groups

8.1. Ethers

The most simple compounds of this type are *methyl ethers* which occur in a range of natural carbohydrates. Methyl esthers belong to the most stable *O*-substituted sugar derivatives, such that per-*O*-methylated hexoses can even be distilled. Traditionally, the labeling of free OH-groups in polysaccharides is effected by methylation, structural analysis being then based on the *O*-methyl sugars obtained on hydrolysis. Methyl ethers are conveniently prepared from methyl bromide, iodide, or sulfate in polar aprotic solvents such as dimethylformamide or dimethylsulfoxide. Agents for deprotonation of the hydroxyl group and for binding the mineral acids liberated include alkali hydroxides or hydrides and barium or silver oxide. With high molecular mass carbohydrates, quantitative deprotonation is best carried out with sodium or potassium methylsulfinyl methanide (the conjugate base of dimethyl sulfoxide) [91].

Benzyl ethers are amongst the most commonly used protecting groups in carbohydrate chemistry [92], as the *O*-benzyl moiety is easily removed by hydrogenolysis (Pd/C, H_2) to yield the respective alcohol and toluene [61]. For the preparation of benzyl ethers, traditional methods involve such reagents as benzyl halides in combination with sodium hydroxide, sodium hydride, or silver oxide.

Triphenylmethyl (trityl) ethers are used mainly for the temporary substitution of primary hydroxyl groups and are usually prepared using trityl chloride in pyridine. Under mild acidic conditions, e.g., acetic acid or boron trifluoride in methanol, the trityl ethers are readily cleaved.

Trimethylsilyl ethers, although extremely sensitive both to base- and acid-catalyzed hydrolysis, are often used in analytical and preparative carbohydrate chemistry. The pertrimethylsilyl ethers of monosaccharides and small oligosaccharides are relatively volatile, highly lipophilic, and thermostable, and therefore, ideal derivatives for gas chromatographic analysis. The trimethylsilyl ethers are rapidly formed in pyridine by using a mixture of hexamethyldisilazane and trimethylchlorosilane [93].

Cellulose ethers (→ Cellulose Ethers) are generally manufactured by the Williamson synthesis: reaction of sodium cellulose (prepared by treating cellulose with 20 to >50 % sodium hydroxide) with an organic halide such as chloromethane or sodium monochloroacetate. The latter reagent produces sodium carboxymethyl cellulose (NaCMC), which is widely used, for example, as a thickening agent in foods. Worldwide production of NaCMC is in the range of several hundred thousand tons per year.

8.2. Esters of Inorganic Acids

Phosphoric acid esters of sugars play vital roles in such fundamental processes as the biosynthesis and metabolism of sugars and, hence, are present in every organism, the most important esters being D-glucose 1-phosphate [*59-56-3*], D-glucose 6-phosphate [*56-73-5*], and D-fructose 1,6-diphosphate [*488-69-7*]. In addition, phosphates of D-ribose and its 2-deoxy derivative form fundamental components of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) and of various coenzymes (→ Nucleic Acids).

α-D-Glucose-1-phosphate

D-Glucose-6-phosphate

D-Fructose-1,6-diphosphate

D-Ribose-5-phosphate

2-Deoxy-D-ribose-5-phosphate

Adenosine-5-phosphate (AMP)

Both chemical and enzymic methods are available for the synthesis of specific phosphates. Chemically, anomeric phosphate esters are usually prepared either from glycosyl halides or other glycosyl donors by reaction with silver dibenzyl phosphate, whilst phosphorylation of nonanomeric hydroxyl groups is effected with specifically blocked sugar derivatives and diphenyl or dibenzyl phosphorochloridate [94]. Biochemically, phosphates are produced by the action of phosphatases on provided substrates [95].

Sulfate Esters. Sulfate groups are present in many biologically important polysaccharides, such as heparin and chondroitin sulfate. Sulfated monosaccharides can be prepared from suitable monosaccharide derivatives by reaction with chlorosulfuric acid in pyridine [96].

Nitrate esters of carbohydrates [97] are not found in nature, yet a large variety ranging from monoesters to peresters have been prepared, favorable conditions being cold nitric acid/acetic anhydride for nonanomeric OH groups, whilst anomeric nitrate esters are accessible via reaction of acyl glycosyl halides with silver nitrate. Sugar mono- and dinitrates are stable crystalline

compounds, such as, e.g., adenosine mononitrate (AMN), the nitrate analog to AMP [98], and the dinitrate of 1,4:3,6-dianhydro-D-glucitol ('isosorbide dinitrate'), which is in broad pharmaceutical use as a coronary vasodilator [99]:

Adenosine 5-nitrate (AMN)

Isosorbide dinitrate

More highly substituted derivatives are heat and shock sensitive, such as, e.g., mannitol hexanitrate or nitrate esters of cellulose (nitrocellulose). These contain as many as three ONO_2 groups per glucose unit. The product with about 13 % nitrogen is the well-known guncotton (→ Cellulose Esters, Chap. 1.), whereas celluloid is nitrocellulose containing about 10 % nitrogen plasticized with camphor; it is one of the oldest known plastics. This plastic was once the principal photographic and movie film, but has been replaced by other films because of its high flammability.

8.3. Esters of Organic Acids

For the esterification of the hydroxyl group of free or partially otherwise blocked sugars, acyl halides or acid anhydrides are usually used, e.g., acetic anhydride/sodium acetate or zinc chloride or acetic anhydride/pyridine readily yield the respective *peracetates*.

Perbenzoylation can be effected with benzoyl chloride in pyridine or benzoyl cyanide in acetonitrile with triethylamine as the catalyst. Tertiary OH groups, present in ketoses or branched-chain sugars, usually require the addition of 4-(dimethylamino)pyridine.

Whereas peracetates and perbenzoates of simple sugars are important intermediates for the preparation of the respective glycosyl halides and, hence, acylated glycals and hydroxyglycals (see Section 8.4), those of some polysaccharides are of industrial relevance. Acetate esters of cellulose are manufactured on a large scale, whereby the degree of acetylation determines the solubility and use: the triacetate (3.0-acetate) is soluble in chloroform, the 2.5-acetate in acetone, and the 0.7-acetate in water. These esters, as well as mixed cellulose acetate/propionate and acetate/butyrate are widely used in the production of lacquers, films, and plastics (→ Cellulose Esters, Chap. 2.1.).

Polysaccharide esters in which the carbohydrate portion is the acid component occur in the plant kingdom in fruits, roots, and leaves. For example, *pectins* are high molecular mass polygalacturonic acids joined by α-(1→4)-glycosidic links, in which some of the carboxylic acid groups are esterified with methanol (→ Polysaccharides, Chap. 3.). In the production of fruit juices the formation of methanol, which can be liberated through the action of pectinesterases, should be avoided. Pectins in which 55 – 80 % of the carboxyl groups are esterified are called high-methoxyl pectins (HM-pectins), and have the important property of gelling at very low concentrations ($\approx$0.5 %) in water in the presence of sugars and acid. Low-methoxyl (LM, $<$50 % of the carboxyl groups esterified) pectins form gels with divalent cations such as a Ca^{2+}; 0.5 % of a low-methoxyl pectin can bind 99.5 % of the water in the gel matrix. These pectins can be used as gelling agents in the production of jellies from fruit juices.

8.4. Acylated Glycosyl Halides

Per-*O*-acylated monosaccharides can be converted smoothly into glycosyl halides by dissolving them in cold solutions of the hydrogen halide in glacial acetic acid (acetates of acid-sensitive oligosaccharides may undergo cleavage of glycosidic bonds). Because of the dominance of the anomeric effect in the pyranosyl cases, the anomer with axial halide is substantially preferred. Accordingly, on acylation and subsequent HBr-treatment, usually performed as a one pot operation, D-glucose yields the 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide ('acetobromoglucose', R = Ac in Fig. 24) or its benzoylated, pivaloylated (R = *tert*-BuCO) or benzylated (R = $C_6H_5CH_2$) analogues [62]. These halides are commonly used directly for glycosylation reactions, which is the basis of the traditional Koenigs-Knorr procedure [100], or

converted into more elaborated glycosyl donors (see Table 1).

Glycosyl halides are also of significance in terms of the use of monosaccharides as inexpensive enantiopure starting materials for the construction of complex, non carbohydrate natural products [101–103], which usually require the reduction of the number of chiral centers paired with the introduction of olefinic or carbonyl unsaturation. Treatment of glycosyl halides with zinc/acetic acid [104] – or, preparatively more efficient zinc/1-methylimidazole in ethyl acetate under reflux [105] – results in reductive elimination to give the glycal, in Figure 24 illustrated with the formation of tri-*O*-acetyl-D-glucal. Simple 1,2-elimination of hydrogen bromide using diethylamine in acetonitrile in the presence of tetrabutylammonium bromide or by 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in DMF [106], [107] yields the respective 2-hydroxyglycal esters. The D-glucose-derived benzoylated example in Figure 24 is an ester of the enol form of 1,5-anhydro-D-fructose.

Figure 24. Formation of glycosyl and 2-oxoglycosyl ('ulosyl') bromides from peracylated monosaccharides, as exemplified for the D-glucose case, and their conversions into glucal and 2-hydroxyglucal esters

Endowed with high crystallinity and shelf stability, the hydroxyglycal esters are of considerable preparative interest not only for the generation of a plethora of other unsaturated compounds, e.g., pyranoid enones [108] and enolones [102], [109], but also as precursors for the highly versatile ulosyl bromides, produced in high yields simply by exposure to NBS or bromine in the presence of ethanol [110], [111]. The utility of these ulosyl bromides as glycosyl donors in the straightforward synthesis of β-D-mannosides has been amply demonstrated [62], [63], [112].

8.5. Acetals

Acetals are generally derived from the reaction of an aldehyde or ketone – benzaldehyde and acetone being the most common – with a geometrically suitable diol grouping, of which there is a large variety in free sugars, glycosides, and alditols [113–115]. The reactions are normally carried out in the reagent aldehyde or ketone as solvent with an electrophilic catalyst (H_2SO_4 or $ZnCl_2$). Acetal formation under these conditions is thermodynamically controlled and usually very specific. Ketones such as acetone or cyclohexanone predominantly bridge vicinal diols to form five-membered cyclic products (1,3-dioxolanes) as exemplified by the di-*O*-isopropylidene derivatives of D-glucose ('diacetone-glucose'), D-galactose and D-mannitol:

Aldehydes, however, show a distinct preference for 1,3-diols, as illustrated by the six-membered 4,6-*O*-benzylidene acetals of methyl D-glucoside and D-galactoside.

Introduction of cyclic acetal groups into sugars is simple and satisfactory in terms of yields. As cyclic acetals are stable towards alkali, the entire armory of organic reactions requiring basic conditions can be applied, and due to their ready removal with mild acid (e.g., 90 % aqueous trifluoroacetic acid at room temperature), they provide indispensable intermediates in preparative carbohydrate chemistry.

9. Carbohydrates as Organic Raw Materials

As our fossil raw materials are irrevocably decreasing – the end of cheap oil is realistically prognosticated for 2040 at the latest [116–118] – and as the pressure on our environment is building up, the progressive changeover of chemical industry to renewable feedstocks emerges as an inevitable necessity [118], [119].

The terrestrial biomass is considerably more complex than fossil raw materials, constituting a multifaceted accumulation of low and high molecular mass products. Carbohydrates, the most abundant of these materials, aside their traditional uses for food, lumber, paper and heat, are the major biofeedstocks to develop industrially and economically viable organic chemicals that are to replace those derived from petrochemical sources.

The bulk of the annually renewable carbohydrate-biomass consists of polysaccharides, yet their nonfood utilization is confined to textile, paper, and coating industries, either as such or in the form of simple esters and ethers. Organic commodity chemicals, however, are low molecular mass products; hence, they are more expediently acquired from low molecular mass carbohydrates than from polysaccharides. This in turn means that polysaccharides usually must be hydrolyzed before being further processed to organic commodity chemicals.

Table 3 lists the availability and bulk-quantity prices of the eight least expensive sugars – all well below €10/kg – as compared to some sugar-derived compounds and basic chemicals from petrochemical sources. The result is stunning, since the five cheapest sugars, some sugar-alcohols, and sugar-derived acids are not only cheaper than any other enantiopure product, such as hydroxy- or amino acids, but they compare favorably with basic organic bulk chemicals such as acetaldehyde or aniline. Actually, the first three of these sugars, sucrose, glucose, and lactose, are in the price range of some of the standard organic solvents.

Table 3. Annual production volume and prices of simple sugars, sugar-derived alcohols, and acids as compared to some petrochemically derived basic chemicals and solvents

	World production∗, t/a	Price ∗∗, €/kg
Sugars		
Sucrose	130 000 000	0.30
D-Glucose	5 000 000	0.60
Lactose	295 000	0.60
D-Fructose	60 000	1.00
Isomaltulose	50 000	2.00
Maltose	3000	3.00
D-Xylose	25 000	4.50
L-Sorbose	60 000	7.50
Sugar alcohols		
D-Sorbitol	900 000	1.80
D-Xylitol	30 000	5.00
D-Mannitol	50 000	8.00
Sugar-derived acids		
D-Gluconic acid	60 000	1.40
L-Lactic acid	> 100 000	1.75
Citric acid	500 000	2.50
L-Tartaric acid	35 000	6.00
Amino acids		
L-Lysine	40 000	5.50
L-Glutamic acid	500 000	7.00
Basic chemicals		
Aniline	1 300 000	0.95
Acetaldehyde	900 000	1.15
Adipic acid	1 500 000	1.70
Solvents		
Methanol	25 000 000	0.15
Toluene	6 500 000	0.25
Acetone	3 200 000	0.55

∗ Reliable data are only available for the world production of sucrose, the figure given referring to the crop cycle 2000/2001 [23]. All other data are average values based on estimates from producers and/or suppliers, as the production volume of many products is not publicly available.
∗∗ Prices given are those attainable in early 2002 for bulk delivery of crystalline material (where applicable) based on pricing information from sugar industry (sugars) and *The Chemical Market Reporter* **2002**, no. 2, 16 – 19 (acids, basic chemicals, and solvents). The listings are intended as a benchmark rather than as a basis for negotiations between producers and customers. Quotations for less pure products are, in part, sizably lower, e.g., for the commercial sweetener "high fructose syrup", which contains up to 95 % fructose, and, thus, may readily be used for large-scale preparative purposes.

Despite their large-scale accessibility, chemical industry, at present, utilizes these mono- and disaccharides only to a minor extent as feed-

stock for organic chemicals. This is amply documented by the fact that of the 100 major organic chemicals manufactured in the USA in 1995 [120], only seven were derived from biofeedstocks, and five of these – ethanol, sorbitol, citric acid, lysine, and glutamic acid – used carbohydrates as the raw material source. Intense efforts within the last decade to boost the production of organic chemicals from the sugars in Table 3 [121–127] have not basically changed this picture.

There are various reasons for that: at present, the use of fossil raw materials is more economic and the process technology for conversion of petrochemical raw materials into organic chemicals is exceedingly well developed and basically different from that required for transforming carbohydrates into products with industrial application profiles. This situation originates from the inherently different chemical structures of the two types of raw materials, of which the essence is manifested in their structure-based names.

Fossile Resources:	Renewable Resources:
HYDRO-CARBONS	CARBO-HYDRATES
C_nH_{2n+2}	$C_n(H_2O)_n$
oxygen-free,	overfunctionalized with
lacking functional groups	hydroxyl groups

Our fossil resources are *hydrocarbons*, distinctly hydrophobic, oxygen-free, and lacking functional groups, annually renewables are *carbohydrates*, overfunctionalized with hydroxyl groups and pronouncedly hydrophilic in nature. Needless to say, that the methods required for converting carbohydrates into viable industrial chemicals are diametrically opposed to those prevalent in petrochemical industry: microbial transformations or chemical processing with reduction of oxygen content and introduction of C=O and/or C=C unsaturation, or preferably both.

9.1. Microbial Synthesis

Microbial processing by direct fermentation of carbohydrates can be used to synthesize a large number of organic chemicals, yet only a few have clearly reached commodity status. They are *ethanol* (fermentation ethanol as distinguished from synthetic ethanol produced by hydration of ethylene), *citric acid* (from molasses by *Aspergillus niger*), *glutamic acid* and *lysine* (from glucose by *Brevibacterium lactofermentum* and others), and *gluconic acid* (from glucose by *Gluconobacter suboxydans*). Together, these chemicals have a sizable annual production (cf. Table 3), however, questions of how and when other microbially synthesized commodity chemicals will play a larger role in the world's chemical markets remain to be answered.

By contrast, there is a broad range of specialty chemicals that are manufactured today by microbial conversion of carbohydrate feedstocks, usually products with molecular structures too complex for conventional chemical synthesis. Examples are antibiotics (penicillins, kanamycins, tetracyclins) and vitamin C, B_2 (riboflavin), and B_{12} (cyanocobalamin). The possibility, however, for production of further high-value-added specialty chemicals or pharmaceuticals from carbohydrates is almost unlimited as long as the appropriate organism and substrate are allowed to interact under suitable conditions [128].

9.2. Chemical Conversions

Presently, the dominant methods of converting carbohydrates to organic chemicals – be it bulk, intermediate or fine chemicals, pharmaceuticals, agrochemicals, high-value-added specialty chemicals, or simply enantiopure building blocks for organic synthesis – are chemical.

9.2.1. Furan Derivatives

Furfural appears to be the only large-volume chemical (200 000 t/a) produced from carbohydrate sources, usually agricultural and forestry wastes [51], [52] (→ Furan and Derivatives, Chap. 3.). Due to its ready accessibility, the ensuing chemistry of furfural is well developed, providing a host of highly versatile industrial chemicals by simple straightforward operations (Fig. 25): furfuryl alcohol and its tetrahydro derivative by hydrogenation of furfural, furfurylamine through reductive amination, furoic acid by oxidation, and furanacrylic acid (Perkin reaction) or furylidene ketones via aldol condensations. Furfural is also the key chemical for the

commercial production of furan (through catalytic decarbonylation) and of tetrahydrofuran by hydrogenation, thereby providing a biomass-based alternative to its petrochemical production via dehydration of 1,4-butanediol. Further importance of these furanic chemicals results from their ring-cleavage chemistry, which has led to a variety of other established chemicals, e.g., levulinic acid (4-oxovaleric acid) and maleic anhydride [52], [129].

The bulk of the furfural produced is used as foundry sand linker in the refining of lubricating oil, and, together with furfurylalcohol and its tetrahydro derivative, enters into condensations with formaldehyde, phenol, acetone, or urea to yield a variety of resins of complex, ill-defined structures, yet excellent thermosetting properties, most notably high corrosion resistance, low fire hazard and extreme physical strength [52], [130].

5-(Hydroxymethyl)furfural (HMF). Like many petroleum-derived basic organic chemicals, e.g., adipic acid and hexamethylenediamine, 5-hydroxymethylfurfural (HMF) is a six-carbon commodity with high industrial potential, and, thus, has been termed "a key substance between carbohydrate chemistry and mineral oil-based industrial organic chemistry" [26]. It is readily accessible from fructose, or inulin hydrolysates by acid-induced elimination of three moles of water [53] and even a pilot-plant process has been developed [26].

Of high industrial potential as intermediate chemicals are the various HMF-derived products (Fig. 26), for which well worked-out, large scale-adaptable production protocols are available. Of these products, 2,5-bis(hydroxymethyl)furan, 5-hydroxymethyl-2-furoic acid, and the 2,5-dicarboxylic acid have extensively been exploited for the preparation of furanoic polyesters [136]. The diol has been reacted with various aliphatic and aromatic diacids; the ethyl ester of 5-hydroxymethylfuroic acid, upon polycondensation, gave a mixture of linear and cyclic products, whereas the furan diacid has been poly-esterified with a series of aliphatic diols or bisphenols. Even an all-furanic polyester has been successfully prepared from its respective monomeric components [136].

Another obvious outgrowth from the furan-2,5-dicarboxylic acid and the respective diamine was the generation of furanic polyamides, as they could potentially replace adipic or terephthalic acid, and, correspondingly, hexamethylenediamine or *p*-diaminobenzene in polyamides (see Section 9.2.5).

Despite this impressive array of useful HMF-derived intermediate chemicals, it is, as of now, not produced on an industrial scale. Obviously, the economic preconditions are not yet favorable enough. A recent assessment of the economics of HMF against competitive petrochemical raw materials [137] gives ample evidence thereof: prices of naphtha and ethylene are in the €150 – 400/t range, those of crude inulin or fructose (≈ €1000/t) give rise to an HMF-marketing price of at least €2500 per ton – too expensive at present for a bulk-scale industrial product. Accordingly, as long as the economic situation favors fossil raw materials, applications of HMF lie in high value-added products, such as pharmaceuticals or special niche materials. Prototype for this outlet is Ranitidine [138], an efficient antiulcer drug due to its potent oral inhibition of histamine-induced gastric acid secretion:

Ranitidine

Furans with a Tetrahydroxybutyl Side Chain. Another simple, one-step entry from hexoses to more highly substituted furans involves their $ZnCl_2$-mediated reaction with 1,3-dicarbonyl compounds such as ethyl acetoacetate or 2,4-pentanedione. As only the first

Figure 25. Versatile furanic commodity chemicals derived from pentosans in agricultural wastes (corn cobs, oat hulls, wood chips, bagasse)

Figure 26. Versatile intermediate chemicals derived from hydroxymethylfurfural (HMF)

Key	A	Ag_2O, 100 °C, 75 % [130]	E	Pt, C / H_2, quant. [132]

two sugar carbons contribute to the formation of the furan, a distinctly hydrophilic tetrahydroxylbutyl side chain is introduced into the heterocycle. D-Glucose, e.g., smoothly and efficiently provides furans with D-*arabino*-configuration in the polyol fragment [139], [140], which can be shortened oxidatively to the dicarboxylic acid or a variety of other furanic building blocks:

9.2.2. Pyrones and Dihydropyranones

The bulk scale-accessible mono- and disaccharides listed in Table 3 are preferentially adopting the pyranose cyclohemiacetal forms, from which efficient reaction pathways lead to an unusually large variety of unsaturated pyranoid building blocks, such as pyrones, dihydropyrans, and dihydropyranones.

The γ-pyrone kojic acid is readily obtained from D-glucose either enzymatically by *Aspergillus oryzae* (growing on steamed rice) [141] or chemically via pyranoid 3,2-enolones [102], [109]. An isomeric α-pyrone is produced from D-glucose by oxidation to D-gluconic acid and acetylation (1 h, 80 °C, 90 %) [142]. Both, at present, are of little significance as starting materials for preparative purposes, despite a surprisingly effective route to cyclopentanoid products [143] which are surmised to have industrial potential.

Table 4. Enantiopure six-carbon building blocks readily accessible in 3 – 5 straightforward steps from D-glucose via D-glucal ester as key intermediate (R = Ac, Bz) [107], [144] (R' = Me, Et)

Of higher interest, at least with respect to their extensive use for the total synthesis of non carbohydrate natural products [101], [102], are the bevy of enantiopure six-carbon building blocks of the dihydropyran and dihydropyranone type in Tables 4 and 5, all compounds depicted being readily accessible from D-glucose in no more than three to five straightforward steps [102], [144].

Table 5. Pyranoid building blocks from D-glucose via hydroxyglucal esters (R = Ac, Bz; R′ = Me, Et) [106] as key intermediates.

Some of these pyranoid building blocks are accessible even more directly, e.g., levoglucosenone, which has been used for the synthesis of a diverse variety of natural products [149]. Although the yield attainable from pyrolysis of waste paper [150] is low (3 – 4 %), relative large quantities can be amassed quickly. Similarly convenient are the preparations of the three glycosylated dihydropyranones requiring two, three, and four steps from maltose, sucrose, and lactose, respectively:

Ac = acetyl; Bz = benzoyl; Pv = pivalolyl

All of these pyranoid building blocks are enantiopure, and have a unique, highly diverse array of functional groups to which the huge arsenal of preparative organic methods can be applied directly, reflecting the extensive use of these building blocks in the total synthesis of non carbohydrate natural products in enantiopure form [101], [102], [149]. They have found little use, though, as high-value-added specialty chemicals. However, if suitable targets and appropriate preparative outlets can be found, particularly along pharmaceutical objectives towards biologically hopeful compound libraries via combinatorial techniques, these pyranoid building blocks are apt to become a plethora of attractive, industrially relevant specialty chemicals.

9.2.3. Sugar-Derived Unsaturated *N*-Heterocycles

Although transformation of sugars into trace amounts of *N*-heterocycles occurs extensively on exposure of foods to heat (Maillard reaction [59]), and despite the fact that various nitrogen heterocycles have been generated from saccharide derivatives [151], synthetic procedures meeting preparative standards are exceedingly scarce. Recent improvements of existing procedures and the development of new methodologies have led to the more ready access to various *N*-heterocycles from carbohydrates. Examples are imidazoles, pyrroles, pyrazoles, pyridines, and quinoxalines which due to their derivation from sugars have hydrophilic side chains.

Pyrroles. The formation of pyrroles by heating a glycerol solution of the lactose-derived ammonium salt of galactaric acid [152] over a free flame [153] appears to be the production process from a carbohydrate source giving the highest yield (40 %). However, this process does not seem to be utilized industrially, neither in this nor in modified form.

2,5-Disubstituted pyrroles are accessible from carbohydrate sources via HMF in a preparatively straightforward reaction sequence, involving photooxidative furan ring opening and cyclization of the saturated 2,5-diketones with ammonia or amines [154]:

These reaction sequences can directly be transferred to GMF, leading to pyrroles carrying an additional glucosyl residue [154]. Pyrroles with an equally hydrophilic tetrahydroxybutyl substituent are available from D-glucosamine by exposure to acetylactone or ethyl acetoacetate under mildly basic conditions [155] or in a one-pot reaction from D-fructose by heating with acetylacetone and ammonium carbonate in DMSO [156].

The hydroxylated side chain can, of course, be oxidatively shortened to give a variety of simple pyrrole building blocks, cyclized to a furanoid ring. These compounds may be considered as *C*-nucleosides [155].

Pyrazoles. An expeditious four-step approach to 1-phenylpyrazol-3-carboxaldehydes with a 5-hydroxymethyl, 5-dihydroxyethyl, or a 5-glucosyloxymethyl substituent has been elaborated starting from D-xylose [157], D-glucose, and isomaltulose [158], respectively.

The osazone of D-xylose, nearly quantitatively formed on reaction with phenylhydrazine, straightforwardly cyclizes to the pyrazole upon addition to refluxing acetic anhydride. Subsequent removal of the *N*-acetylphenylhydrazone residue with formaldehyde/acetic acid and de-*O*-acetylation provides a pyrazole-aldehyde (57 % overall yield from D-xylose), a versatile heterocyclic building block, useful in the synthesis of pharmaceuticals or monomers for the production of polyamides and polyesters, e.g., in the form of its the diamino and diol derivatives [157]:

Imidazoles. Various imidazoles carrying hydrophilic substituents in the 4-position are readily accessible in one-pot procedures from the standard monosaccharides. Of those, the formation of 4-hydroxymethylimidazole by Cu(II)-promoted reaction of monosaccharides with formaldehyde and conc. ammonia [159] is rather unique, because obviously retroaldolization to glyceraldehyde and dihydroxyacetone is involved. The retroaldol fission can be partially suppressed when heating a monosaccharide, D-fructose for instance, with formamidinium acetate in liquid ammonia in a pressure vessel [160], or with formamidinium acetate in the presence of boric acid and hydrazine [161]. The latter reaction obviously proceeds via a boric acid complex of the bishydrazone of D-glucosone (2-ketoglucose).

Conditions
A CH_2O, aq. NH_3, $CuCO3/Cu(OH)_2$, 2 h, 100 °C, [158]
B $HC(NH)NH_2 \cdot HOAc$/liq. NH_3, 15 h, 75 °C, [159]
C $N_2H_4/HC(NH)NH_2 \cdot HOAc$/aq. HOAc, H_3BO_3, 3 h reflux, [160]

These conditions can be readily applied to pentoses or disaccharides, as exemplified with D-xylose [160] and isomaltulose [161] in for one-pot procedures acceptable yields:

3-Pyridinols. The conversion of pentosans or pentoses into 3-pyridinol can be effected in a practical three-step sequence, involving acid-induced dehydration to furfural, reductive amination to furfurylamine, and subsequent oxidation wit hydrogen peroxide [134], [162], the last step conceivably proceeding through the stage of a 2,5-dihydroxy-2,5-dihydrofurfurylamine, which gives the pyridine nucleus via dehydration to a 5-aminopentenal intermediate and intramolecular aldimine formation. The pyridinol is an important intermediate in the preparation of herbicides and insecticides [163] as well as cholinergic drugs of the pyridostigmine type.

For the conversion of furfurylamines with oxidizable hydroxyl groups, e.g., those derived from fructose via HMF, the multistep process to the hydroxymethyl-pyridinol can be effected in a one-pot procedure simply by treatment with bromine in water-methanol at 0 °C [164] (see bottom of the next page).

Quinoxalines. Useful one-pot procedures are also available for the conversion of various monosaccharides into tetrahydroxybutyl substituted quinoxalines, the preparatively most favorable conditions seem to be reaction of fructose with hydrazine, *o*-phenylenediamine and boric acid in dilute acetic acid with bubbling oxygen through the solution [165], the decisive intermediate being the bishydrazone of D-glucosone:

R = H (45 %) [166], R = Ph (90 %) [167]

On briefly refluxing the quinoxaline in aqueous acid with excess hydrazine or phenylhydrazine, a surprising oxidative cyclization takes place to form the trihydroxypropyl-substituted flavazols [166], [167].

9.2.4. Sugar-Based Surfactants

Utilization of cheap, bulk-scale accessible sugars as the hydrophilic component and fatty acids or fatty alcohol as the lipophilic part provides nonionic surfactants which are nontoxic, nonskin-irritating and fully biodegradable. The industrially relevant surfactants along this route are fatty acid esters of sorbitol and sucrose, fatty acid amides of 1-methylamino-1-deoxy-D-glucitol, and, most pronounced in terms of volume produced, fatty alcohol glucosides, the so-called alkyl polyglucosides (→ Surfactants, Chap. 7.4.; → Laundry Detergents, Chap. 3.1.2.6.).

Fatty Acid Esters of Sorbitol (Sorbitan Esters). Sorbitol, well accessible by catalytic hydrogenation of D-glucose (see Table 3), readily undergoes dehydration to "sorbitan" which constitutes a mixture of sorbitol, its 1,4-anhydro and 1,4:3,6-dianhydro derivatives, the exact composition depending on the conditions employed, usually acid catalysis. Esterification of this mixture is generally carried out with fatty acids or their methyl esters at 200 – 250 °C with 0.1 N NaOH. Depending on the amount of fatty acids used, sorbitan monoester ('SMS', R = C_{16}/C_{18} acyl), di- or triester ("SMT") are formed:

"Sorbitan Monoester" (SMS): R = C_{16}-C_{18} acyl

SMS is dispersible in water and soluble in fats and oils and has low hydrophilic lipophilic balance (HLB) values, besides as a surfactant SMS finds use as an emulsifier in desserts [168].

Sucrose Fatty Acid Esters. Surfactants based on sucrose have gained limited acceptance industrially due to the instability of its

intersaccharidic bond, and its insolubility in conventional organic solvents. This requires the use of the rather toxic and expensive dimethylformamide or dimethylsulfoxide for effecting transesterification with fatty acid methyl esters and complete removal of the solvents. Alternately, transesterification of fats with sucrose without a solvent is also possible. In either case, the resulting sucrose monoester (if 1:1 molar ratios have been used in the esterification process) is not a defined product acylated exclusively at the primary glucose-6-OH, as indicated in the formula, but at the other primary and some of the secondary OH groups as well:

Sucrose fatty acid monoesters, presently produced at a 4000 t/a only, are mostly used in the food industry as emulsifiers and in cosmetic formulations because of their attractive physiological properties.

Whilst sucrose fatty acid mono- or diesters are biodegradable, fully or nearly completely esterified analogs (octa- or heptaesters) are not. The sucrose molecule is fully encased in a mantle of long-chain alkyl groups, so that enzymes have no way of binding to the sugar, which is a prerequisite for degradation. Thus, Olestra [169], a sucrose fatty acid hepta-/octaester, which has the consistency of an oil or a solid depending on the nature of fatty acid used, can be used as a noncaloric fat ('fat-free fat' [170]) in food applications including frying, due to its thermal stability.

***N*-Methyl-*N*-acyl-glucamides (NMGA).** Reductive amination of D-glucose with methylamine smoothly generates the respective aminoalditol, 1-methylamino-1-deoxy-D-glucitol, which on amidation with fatty acids gives the corresponding fatty acid amides, carrying a methyl group and a pentahydroxylated six-carbon chain at the amido nitrogen.

The NMGA's possess highly advantageous ecological and toxicological properties which brought about their use as surfactants, cleansing agents and cosmetic applications [171], [172] (→ Laundry Detergents, Chap. 3.1.2.5.).

Alkylpolyglucosides (APG) [173]. Presently produced in two plants with a capacity of up to 40 000 t/a each, APG's are by far the most important nonionic surfactants. Alkylpolyglucosides are fatty alcohol glucosides with an alcohol chain length normally between C_8 and C_{14}. Their industrial synthesis either comprises a direct acid-catalyzed Fischer glycosidation of glucose (in the form of a syrupy starch hydrolysate) or starch itself. The alternate process consists of two stages, the first being Fischer glycosidation with *n*-butanol to butyl glycosides which are subsequently subjected to acid-promoted transacetalization:

Alkyl Polyglucosides
(x = 0.3-0.7; m= 4-7)

APG's are not skin-irritating, have good foaming properties, and are readily biodegradable, hence are widely used in manual dishwash-

ing detergents and in formulations of shampoos, hair conditioners, and other personal care products.

9.2.5. Hydrophilic Monomers of Polyamides

Polyamide production worldwide amounted to about 5.8×10^6 t in 1998 [174]. More than 90 % of these polyamides are based on six-carbon monomers, i.e., caprolactam (nylon 6), and adipic acid/hexamethylenediamine (nylon 66).

As six-carbon compounds in the form of hexoses are abundantly available in nature, substantial efforts have been made to derive monomers suitable for polyamidation from the bulk scale-accessible hexoses. This approach becomes particularly evident, when considering the large variety of amincarboxylic acids, dicarboxylic acids, and diamines (Table 6), that are accessible from the common six-carbon sugars [175], [176].

Of the myriad of possible combinations of these sugar-derived monomers either with themselves or with the common, petrochemically derived diamines and dicarboxylic acids, an immense number have been realized. In the following only a few of the respective polyamides are exemplarily covered.

Solution or interfacial polycondensation of galactaric acid dichloride in its acetylated form with various aliphatic and aromatic diamines resulted in a series of polyamides [175], [177], the one resulting from 1,6-diaminohexane resembling a nylon-6,6 in which half of the hydrogens of the methylene chain have been substituted by acetoxy groups (R = Ac). These can be deacylated with aqueous ammonia to give the tetra-hydroxylated nylon 66:

Table 6. Sugar-derived six-carbon building blocks suitable for polyamidation [175], [176]

	D-Glucaric acid	(Glucose)
	D-Galactaric acid	(Lactose)
	Furan-2,5-dicarboxylic acid	(Fructose)
	1,6-Diamino-1,6-dideoxy-D-glucitol	(Glucose)
	2,5-Diamino-1,4:3,6-dianhydro-sorbitol	(Glucose)
	2,5-Bis(aminomethyl)furan	(Fructose)
	6-Amino-D-gluconic acid lactam (R = H, CH_3)	(Glucose)

In the case of D-glucaric acid, the use of its 3,6-lactone monomethyl ester proved advantageous to generate stereoregular polyglucaramides, effected with an impressive array of aliphatic and aromatic diamines [178]:

R – $-(CH_2)_x-$ with x – 2-12; $-CH_2C_6H_4CH_2-$;

$-(CH_2)_3NH(CH_2)_3-$; $-(CH_2)_3N(CH_2)_3-$; (CH_3)

$-(CH_2)_2O(CH_2)_2O(CH_2)_2-$; $-CH_2CH(CH_2)_2-$ (CH_3)

Sugar-based "quasi-aromatic" monomers for polyamides, i.e., the furan-2,5-dicarboxylic acid, appear particularly relevant as they embody the potential to replace petrochemically derived terephthalic or isophthalic acid in the present industrial products. Similar potential pertains to the furanic 1,6-diamine as a substitute for *p*-phenylenediamine. Indeed, a series of such furanic polyamides has been prepared [179] using the furan dicarboxylic acid and aliphatic as well as aromatic diamines. Of these, the polyamide resulting from condensation of furan-2,5-dicarboxylic acid with *p*-phenylenediamine, an analog of Nomex and Kevlar, has particularly promising decomposition and glass temperature parameters [180], distinctly better than those found for the all-furanic polyamide:

Nomex

Kevlar

In spite of the impressive array of highly useful products – with respect to their application profiles they compare on the market favorably with the well-known polyamides – none of these sugar-derived polyamides is, at present, produced on an industrial scale. The reasons are purely economic because the products derived from fossil raw materials are still cheaper by a factor of 5 on the average. Eventually though, with the end of cheap oil being prognosticated for 2040 at the latest [116], and the increasing pressure on the environment, this at present untoward situation for products from carbohydrate feedstocks will be changing.

Abstract

The article contains sections titled:

1. Introduction
2. Diamond
2.1. General Sources
2.2. Properties and Structure of Natural Diamond
2.3. Diamond Synthesis
2.3.1. HPHT Synthesis
2.3.2. The Diamond Chemical Vapor Deposition (CVD) Process
2.3.3. Diamond CVD Techniques
2.3.3.1. Nonthermal Plasma CVD
2.3.3.2. Thermal Plasma Diamond CVD
2.3.3.3. Other CVD Techniques
3. Graphite
3.1. Single Crystal
3.2. Natural Graphite
3.3. Artificial Graphite
4. Carbon and Graphite Materials
4.1. Carbon and Graphite Artifacts
4.1.1. Manufacture
4.1.2. Properties
4.1.3. Applications
4.1.4. Economic Aspects
4.2. Other Classes of Carbon
4.2.1. Glassy Carbon

4.2.2. Pyrocarbon and Pyrographite
4.3. Graphite Compounds
4.3.1. Surface Complexes
4.3.2. Graphite Intercalation Compounds
4.4. Expanded Graphite and Graphite Foil Derived from Intercalation Compounds
5. Activated Carbon
5.1. General Aspects
5.2. Carbonaceous Adsorbents
5.2.1. Types of Carbonaceous Adsorbents
5.2.2. Chemical Properties
5.2.3. Mechanical Properties
5.2.4. Adsorption Properties
5.2.5. Quality Control
5.3. Production
5.3.1. General Aspects
5.3.2. Raw Materials
5.3.3. Activating Furnaces
5.3.4. Methods of Activation
5.3.4.1. Chemical Activation
5.3.4.2. Gas Activation
5.3.5. Granular and Pelletized Carbons
5.3.6. Carbon Molecular Sieves
5.3.7. Further Treatment
5.3.8. Impregnation
5.4. Applications
5.4.1. Gas-Phase Applications
5.4.1.1. Solvent Recovery
5.4.1.2. Process-Gas and Air Purification
5.4.1.3. Gas Separation
5.4.1.4. Gasoline Vapor Adsorption
5.4.1.5. Flue Gas Cleaning
5.4.2. Liquid-Phase Applications
5.4.2.1. Water Treatment
5.4.2.2. Micellaneous Liquid-Phase Applications
5.4.3. Impregnated Activated Carbon
5.4.4. Catalysts and Catalyst Supports
5.5. Regeneration and Reactivation
5.6. Economic Aspects
6. Carbon Black
6.1. Physical Properties
6.2. Chemical Properties
6.3. Raw Materials
6.4. Production Processes
6.4.1. Furnace Black Process
6.4.2. Gas Black and Channel Black Processes
6.4.3. Lamp Black Process
6.4.4. Thermal Black Process
6.4.5. Acetylene Black Process
6.4.6. Other Manufacturing Processes
6.4.7. Oxidative Aftertreatment of Carbon Black
6.4.8. Environmental Problems
6.5. Testing and Analysis
6.6. Storage and Transportation
6.7. Uses
6.8. Economic Aspects
6.9. Toxicology and Occupational Health
7. Fullerenes
7.1. History
7.2. Production

7.2.1. Vaporization of Graphite
7.2.2. Fullerene Synthesis by Combustion
7.2.3. Pyrolysis of Naphthalene
7.3. Structure and Nomenclature
7.4. Physical Properties
7.5. Chemical Properties
7.5.1. Addition Reactions
7.5.2. Hydrogenation
7.5.3. Halogenation

1. Introduction

Otto Vohler, Gabriele Nutsch, Gerd Collin, Ferdinand von Sturm

Carbon is the sixth element of the periodic table with an atomic mass of 12.01115 ± 0.00005. It consists of 98.89 % of the isotope ^{12}C, 1.11 % of the isotope ^{13}C, and several unstable isotopes with mass numbers between 9 and 16. The isotope ^{14}C, which is formed in the atmosphere by the reaction $^{14}N(n,p)^{14}C$, is used in archaeology for age determination and tracing of chemical compounds [29]. The half-life of this β emitter is about 5570 years.

Carbon is the thirteenth most abundant element. The earth's crust, including the lithosphere, hydrosphere, and atmosphere, contains about 3×10^{16} t of carbon, which corresponds to 0.09 wt % or 0.15 atom %, most of which is present as compounds, and only a small portion in elementary form. The carbon contents of sea water, the atmosphere, and the biosphere are about 4×10^{13} t, 4×10^{11} t, and 3×10^{11} t, respectively.

Carbon exists in several allotropic modifications (Fig. 1). The modifications differ from one another in the arrangement of the carbon atoms in their crystals (Figs. 2 and 3).

Figure 1. Allotropic modifications of carbon

Figure 2. The three most important allotropic forms of solid elemental carbon and their main derivates [30]

Figure 3. Bonding hybridization and corresponding crystal structure of the carbon allotropes [30]

Diamond is the metastable phase of carbon under standard conditions and can be transformed into graphite by heating above 2000 K [31] (see Fig. 4). The transformation of graphite into diamond (diamond synthesis) is only possible at high temperatures and high pressures [32]. The atoms in the diamond lattice are singly bonded. The four symmetrical sp^3 σ-bonds point to the corners of a regular tetrahedron (Fig. 3). Therefore, diamonds have a rigid and isotropic structure and are usually cubic. Hexagonal diamond (londsdaleite) was first found as a product of diamond synthesis, but meanwhile it has also been discovered in meteorites [33]. According to Fig. 4 diamond can be produced at low pressure by chemical vapor deposition (CVD; see Section The Diamond Chemical Vapor Deposition (CVD) Process).

Graphite is characterized by its layered lattice structure due to association by π-bonds perpendicular to the σ-bonds layers. Hence, graphite is highly anisotropic. However, only a few natural graphites and hot-worked pyrographite samples are nearly perfect crystals. Most carbon materials deviate more or less from the perfect crystal structure. The differentiation between graphite and carbon, a term used for the less perfect structures such as metallurgical coke or charcoal, is only for the sake of convenience. Graphite is the thermodynamically most stable allotrope of carbon at room temperature and pressure (see Fig. 4). It is characterized by double bonds between sp^2 carbon atoms (see Fig. 3). At atmospheric pressure, graphite vaporizes without melting at ca. 3895 – 4020 K. The heat of sublimation depends on the vapor composition. It amounts to 711, 825, and 788 kJ/mol for mono-, di-, and triatomic molecules, respectively. At 4000 K, about 80 % of carbon vapor consists of C_3 molecules. By using a laser-heating technique, a graphite – liquid – vapor equilibrium pressure of 10.7 ± 0.2 MPa at a temperature of about 4000 K was found [34].

Chaoite, a member of the carbyne group, was found in small quantities together with graphite in the rocks of the Nördlinger Ries in Germany, which were transformed by meteoritic impact [35]. Small quantities of other members of the carbyne group were found together with graphite in carbon layers formed by vaporized carbon, in laser-heated carbon, and also in meteorites. The transformation of *sp*-hybridized carbon molecules (carbyne) into diamond by shock wave experiments has been investigated [36]. A common feature of the numerous members of this group are triple bonds [37-39].

Fullerenes are the most recently discovered allotropic form of carbon [40]. In October 1996, R. E. SMALLEY, R. F. CURL, and H. W. KROTO received the Nobel prize for their discovery of the C_{60} cage molecule in 1985. However, the method for their bulk production wass discovered only in 1990 [41]. These all-carbon cage molecules constitute the third allotropic form of carbon. They are composed of more or less deformed sp^2-bonded carbon atoms. Fullerenes are formed in condensing carbon vapor in which linear carbon chains link together and form graphitic sheets. These free-floating sheets cannot tie up the dangling bonds on their edges. Elimination of the dangling bonds by curling up serves the physical tendency to reach the lowest energy level available. Thus, the fullerenes are a pure, finite form of carbon. The two other forms, diamond and graphite, are infinite network solids.

Giant fullerenes in the form of *nanotubes* and *buckyonions* have further expanded the realm of this new form of carbon. The fullerene-related nanotubes are formed by a single-layer graphitic network of hexagons (Fig. 2). The presence of pentagonal or heptagonal carbon rings renders their physical properties different from those of graphite. There are no sp^3 bonds, grain boundaries, or edges, and they contain no hydrogen [30], [42].

Fullerene derivatives can be created by adding endo- or exohedral substituents. This opens the possibility of obtaining a wide range of building blocks for developing new materials with unique properties.

2. Diamond [43-45]

Otto Vohler, Gabriele Nutsch, Ferdinand von Sturm, Erhard Wege

2.1. General Sources

For many centuries, natural diamond has been appreciated as a valuable gem and investment. The first center of mining was India, which was replaced by Brazil in the early 1700s, South Africa in the mid-1800s, and most recently Kongo (formerly Zaire), Australia, Russia, Botswana, and Namibia. Output amounted to ca. 55 × 10^6 ct in 1998, but this does not satisfy the increasing demand for industrially used diamonds. Table 1 lists the diamond mining output of some of major producing countries and the total world mining production in 1998.

The sources of natural diamonds are probably ultrabasic rocks, especially eclogite, which consists essentially of omphacite and pyrope. The famous blue ground of Kimberlite slots is a decomposed eclogite rock containing about 0.5 ct of diamond per tonne. Such primary deposits are found in South Africa, Russia, and Tanzania. Most of occurences of diamond are secondary deposits. From so-called placers, of which the Lüderitzbay deposit in Namibia is an example, diamond is mined explosively.

Less than the half of the mined diamonds can be used for gems; the majority are used for industrial purposes. The prospering interest in industrial diamonds is based on their combination of outstanding properties besides their high hardness, which makes them highly suitable for many applications. Synthetic diamond has been produced commercially for over 30 years [46-48] by high-pressure, high-temperature (HPHT) techniques (see Fig. 4) Synthetic industrial diamond is available in far larger quantities than its natural diamond counterpart. The estimated capacity for synthetic diamond of 100 × 10^6 ct in 1982 increased to 350 × 10^6 ct in 1990 and to more than 500 × 10^6 ct in 1999 (see Table 2). Consequently, synthetic diamond accounts for more than 90 % of the industrial diamond used. Various reports estimate the total industrial diamond output worldwide to be more than 600 × 10^6 ct, valued at (600 – 800) × 10^6 dollars. More than 30 countries produced industrial diamond in 1998. In addition to the countries listed in Table 2, Korea produces synthetic diamond, but specific data on their output could not be confirmed. China and Russia also presumably produce far more than the output given in the table. Thus, two-thirds of industrial diamond output is concentrated in four countries: the United States, Ireland (possibly the world's largest producer), Russia, and South Africa.

Table 1. World diamond mining output in 1998, 10^6 ct

Country	Gem	Industrial	Total

Figure 4. Phase diagram of different carbon modifications

Interest in industrial diamond has been further increased by the more recent discovery [49], [50] that it is possible to produce polycrystalline diamond films or coatings by a wide variety of chemical vapor deposition (CVD) processes from a hydrocarbon gas in an excess of hydrogen. This CVD diamond can show mechanical, tribological, and even electronic properties comparable to those of natural diamond.

2.2. Properties and Structure of Natural Diamond

Diamond is a colorless mineral, generally characterized by its hardness (Mohs hardness 10) and brilliance after cutting. The density is 3.515 g/cm^3 (cf. graphite 2.266 g/cm^3). The lattice of the cubic modification is face-centered with the lattice constant a = 0.3567 nm. The atomic arrangements in diamond is shown in Figure 3. Diamond is tetrahedrally bonded, and all atoms have equal bond lengths of 0.1544 nm and are linked by overlapping sp^3 hybrid orbitals (sp^3 – sp^3 σ-bond). The bonding angle of the covalent hybrid bonds is 109.28°. This contrasts with the hexagonal structure of graphite with trigonal bonding (Fig. 3). The sp^2 – sp^2 σ-bonding is supplemented by p – p π-bonds oriented perpendicularly to the σ-bonds. All σ-bonds lie in the same plane, and the bond angle is 120°. The stacking sequence for the carbon atoms in the diamond structure is ABCABC (Fig. 5 b). It shows a chair configuration (hatched) of puckered hexagonal rings in both the vertical and horizontal stacking directions. The first carbon atom that starts nucleating a new {111} diamond layer is shown in the Figure 5 a (top). By addition of a further carbon atom the basic unit of the structure is obtained. This is also the nucleation kernel for a new plane.

Figure 5. Stacking of carbon atoms in diamond crystals

The color of diamonds can vary from white to pink, yellow, light blue, and even black (carbonado), depending on the incorporated impurities. On the basis of the different characteristics of the IR absorption spectra of natural diamond, a distinction is made between Type I and Type II diamond, with several subgroups. A majority of gem-quality diamonds are of Type I a and contain substitutional nitrogen impurities up to 0.5 atom %. These diamonds have a characteristic, slightly greenish yellow color. Only about 1 % of natural diamonds contains impurities in the form of substitutionally isolated nitrogen atoms. These diamonds are classified as Type I b. All synthetic diamonds belong to this group. Their nitrogen atoms did not havesufficient time to form aggregates, in contrast to the natural diamonds of Type I a, most of which remain deep in the earth's mantle after their formation and are exposed to extremely high temperatures and pressures. During this phase, the majority of the nitrogen atoms can form aggregates.

Diamonds without measurable substitutional nitrogen atoms or aggregates are classified as Type II a. They are very rare in nature; less than 1 % of all diamonds belongs to this group. Their absorption bands are caused only by the vibrational absorption of the lattice that is common to all diamonds. They are often colorless or light pink. Type II a diamonds are electrical insulators like Type I, but have excellent optical and thermal properties. Type II b diamonds containing ca. 1 ppm of boron atoms and even smaller amount of nitrogen impurities are the purest form of naturally occuring diamonds. They are usually blue to bluish gray in color. The presence of boron atoms makes these diamonds to electrical semiconductors.

Diamond crystals cleave well parallel to (111). The cutting hardness is different for the various crystal faces, and this must be taken into consideration when cutting. The coefficient of friction depends on the purity of the surfaces. With increasing degasification, the coefficient rises from about 0.1 to 0.6 [51], [52].

Diamond is known for its combination of its outstanding properties: it has extreme mechanical hardness (ca. 90 GPa, or Mohs hardness 10), it is the strongest known material with the highest bulk modulus (1.2×10^{12} N m^{-2}) and lowest compressibility (8.3×10^{-13} m^2 N^{-1}). Its thermal expansion coefficient at room temperature of 0.8×10^{-6} K^{-1} is comparable with that of low-expansion iron – nickel alloys (Invar). The specific heat is 6.2 J g^{-1} K^{-1} at 300 K, 13.55 J g^{-1} K^{-1} at 500 K and 21.6 J g^{-1} K^{-1} at 1000 K. Diamond Types I and II a are good electrical insulators, with a room-temperature resistivity of about 10^{16} Ω cm. However, diamond can be doped, for example with boron (Type II b), to vary its resistivity over the range 10 – 10^6 Ω cm, so that it becomes a semiconductor with a wide band gap of 5.4 eV.

Diamonds are excellent conductors of heat. Type II a diamond has the highest known thermal conductivity at room temperature of 2×10^3 W m^{-1} K^{-1}, which is five times higher than that of copper. Diamond has a broad optical transparency from the deep - UV to the far - IR“ndash” OK? (Korektur nicht eindeutig auch im Folgenden) region of the electromagnetic spectrum. Moreover, it is biologically compatible and very resistant to chemical erosion and abrasive wear at room temperature. At higher temperatures, it is attacked by oxygen, oxidizing agents, and carbide-forming elements. At temperatures of about 2000 K and above, diamond is converted to graphite, both internally and on the crystal surfaces. The rate of phase transformation increases rapidly with increasing temperature [53].

2.3. Diamond Synthesis

According to the phase diagram (Fig. 4) there are only a few ways to synthesize diamond: by shockwaves (mostly used in Japan), by high pressure and high temperature (HPHT synthesis), and by chemical vapor deposition (CVD) at relatively low pressures and moderate temperatures.

2.3.1. *HPHT Synthesis*

Figure 4 shows how the state of carbon phases depends on temperature and pressure [54]. Diamond is a metastable phase at standard temperature and pressure, and graphite is the only thermodynamically stable carbon phase. The transformation of graphite into diamond is possible at high temperatures and pressures [55-57]. Above 12.5 GPa and temperatures of about 3000 K, graphite spontaneously collapses into polycrystalline diamonds.

The difficulty in the diamond synthesis process has always been the simultaneous achievement of sufficiently high pressures and temperatures. These conditions require special apparatus which was first developed by P. W. BRIDGMAN [58] in the form of a self-sealing high-pressure packing which operated without leaking and permitted hydraulic operation, namely, the unsupported area seal. For the invention of the apparatus to produce extremely high pressures, BRIDGMAN was awarded the Nobel Prize in 1946.

The General Electric process [46-48] uses a modified Bridgman apparatus [59], [60]. In the “catalytic” process, graphite is transformed into diamond by first dissolving it in molten metals and then cystallizing it above equilibrium pressure. Nickel is the most widely used metal for dissolving carbon, for which it has a high solubility (ca. 4 wt % at 1500 °C and 5.7 GPa). Under these conditions, graphite is metastable, and diamond, which is less soluble (ca. 3.6 wt %) crystallizes out. In the past it was assumed that the metals used (e.g., nickel, manganese, iron, cobalt, palladium, platinum, and alloys thereof) act as catalysts. The term catalyst is still frequently used, but it is now clear that the metals serve purely as solvents [61], and that the growth process is analogous to the traveling-zone solvent technique [62].

Any form of carbon can be used as the starting material [63]. Naphthalene initially forms graphite; paraffin wax and sugar are

converted directly to diamond. Even peanuts are transformed to the extent of up to 60 % into diamond at 2000 K and 10 GPa in 5 min.

The belt and multipiston diamond – synthesis apparatus is shown in Figure 6. It consists of two truncated conical pistons and a prestressed cylinder assembly, which forms the reaction chamber. The circular gaps between the sections are filled with conical gaskets made of pyrophyllite, a hydrous aluminium silicate, coated with a thin dusting of hematite (Fe_2O_3) to further increase the friction. The gaskets act as seals, pressure transmitters, and thermal and electric insulators. By using strongly tapered pistons (a and c in Fig. 6) a large piston motion becomes possible without squeezing the pyrophyllite gasket too thin. The compressed gasket in turn provides additional strength by supporting the pistons. This arrangement is suitable for a large volume of starting material, which consists of stacked graphite and metal plates or a mixture of graphite powder and nickel or other group 8 – 10 metal powder, and is heated directly by resistance heating. The current is supplied via pistons, current rings and nickel plates. Since the graphite has the highest resistance in the current path, it is heated to the desired temperature. The nickel melts, dissolves the graphite, and begins to crystallize out diamond. The molten metal film is less than 0.1 mm thick, and the movement of the carbon through this metal film is quite rapid. In a few minutes the nickel film moves through the graphite from both ends to the hotter center, and all graphite is converted to diamond. The pressure is maintained until after current has been cut off and the sample cooled to prevent reversion to graphite. After cooling, the diamonds are separated by dissolving the metal with acids. The average size of the synthetic diamonds is about 0.05 – 0.5 mm. The lifetime of this apparatus with a diameter of up to 40 mm is ca. 100 to 1000 cycles when properly operated. Smaller diamonds are produced only by shockwaves (see Fig. 4).

Figure 6. Belt-type pressure apparatus [139]

a) Top piston; b) Cylinder; c) Bottom piston; d) Gasket assembly; e) Current ring; f) Sample holder; g) Graphite; h) Insulating pill

Diamond crystals can be controlled in size and mechanical properties by varying the process parameters such as the form and nature of graphite, the metal solvent used, temperature, pressure, and time. Grit up to 0.5 mm in size is produced without crushing. Also the shape of the crystals can be controlled by the temperature. Because of this size- and shape-control ability, synthetic diamond grit is generally superior to natural diamond. Cutting blades made from GE diamonds have been manufactured for many years [64], [65]. For cutting rocks or glass, blocky grit sintered in a metal matrix is used. For shaping hard metals and tungsten carbide, a friable grit in a resinoid matrix is preferred. For polishing pastes, the grit is often mixed with olive oil, lithium stearate, and some amorphous silica. There are also diamond compounds for polishing based on water with polyethylene glycol, potassium hydroxide in methanol, and amorphous silica. There is no difference in hardness between synthetic and natural diamond.

About 15 years after the first announcement of industrial diamonds, single crystals in gem quality were also grown by this method [63]. The equipment is similar to that described above, but the large, high-quality crystals must be grown very slowly (about one week is necessary to grow a 5 mm, 1 carat, high-quality diamond crystal) and under much more carefully controlled and stable conditions. This makes gem diamond growth so difficult and expensive.

2.3.2. *The Diamond Chemical Vapor Deposition (CVD) Process*

Chemical vapor deposition (CVD) of diamond films has developed dramatically [66-74] since its initiation in the 1950s [49], [50]. The diamond film deposition process utilizes temperature and pressure conditions under which graphite is the stable form of carbon (see Fig. 4). However, the kinetic factors of the CVD process allow crystalline diamond to be produced by the typical net reaction:

$$CH_4(g) + \text{activation energy} \rightarrow C(\text{diamond}) + 2\,H_2(g)$$

In addition to methane, a wide variety of carbon-containing substances have been used as precursor materials. The diamond CVD process involves chemical reactions in the gas phase as well as at the solid surfaces which cause depositions onto the surfaces (Fig. 7). Usually, the CH_3 radical is regarded as the precursor. This depends on the boundary conditions at the substrate. With high-energy plasma jets, atomic carbon is the most important precursor species.

Figure 7. Diamond CVD process (after [71])

All CVD techniques used for producing diamond films require:

- a particular gas atmosphere and hence, a closed reaction chamber
- a means for activating the gas-phase carbon-containing precursor molecules
- a substrate temperature of about 400 to 1000 °C

– dissolution of the precursor gas in an excess of hydrogen

While HPHT synthesis requires special industrial equipment used by only few companies, the CVD of diamond films can be performed by using more or less the laboratory equipment. Deposition methods are diverse.

The Role of Hydrogen. Hydrogen is a very important species for diamond growth [75]. Hydrogen plays two main roles. First, molecular hydrogen suppresses the formation of aromatics in the gas phase; second, atomic hydrogen activates the surface.

With pure CH_4, growth of a layer also occurs, but it consists of both diamond and unwanted carbon phases (Fig. 8). With hydrogen alone, only etching of both graphite and diamond occurs. The graphitic phases are always more readily etched by reaction with hydrogen atoms than the diamond phase. Therefore, hydrogen atoms should be present in higher than equilibrium concentration to obtain successful diamond growth and etching of non-diamond carbon phases.

Figure 8. Schematic depiction of the growth of diamond (dark arrows) and removal of unwanted carbon phases (light arrows)

Due to the excess of hydrogen the diamond surface is almost fully saturated with hydrogen during the growth process (step 1 in Fig. 9). Desorption of bound hydrogen by incoming atomic hydrogen creates vacant sites or surface radicals (step 2 in Fig. 9). These vacant sites can be refilled by atomic hydrogen (step 3 a in Fig. 9), or H atoms can be added to unsaturated carbon – carbon bonds. Thereby, conversion into sp^3 bonds at low temperatures or gasification of sp^2 bonds at high temperatures takes place, and diamond growth occurs (step 3 b in Fig. 9).

Figure 9. C, H bounded C and H atoms, Ⓗ•, ©• excited atoms

Without activation of the gas by plasma or other energetic sources, the concentration of atomic hydrogen, and therefore the number density of active sites, is low. Hence, the film – growth rate is very low.

The Role of Substrate Temperature. The deposition of polycrystalline diamond films occurs in a surface temperature range of about 850 – 1500 K. The lower limit approaches about 700 K and is nearly independent of the deposition technique [72], [73], [76], but it depends on the precursor used, the growth rate is very low, and non-carbon phases are implanted into the layer [77], [78]. However, the growth rate can be enhanced by using halogenated precursors [79]. The surface chemistry depends strongly on the surface temperature. At low temperatures, the rate of creation of active sites is low. Increasing the temperature also increases this creation rate. Above about 1500 K the number density of active sites decreases due to thermal decomposition and subsequent graphitization. The sp^2 bonds are rapidly etched by the hydrogen atoms.

At too low surface temperatures the condensation of aromatics can lead to amorphous carbon phases. Therefore, an efficient diamond growth rate can be controlled by the surface temperature, the absolute number density of the carbon-containing species and atomic hydrogen, and the ratio of the two.

By varying the substrate temperature, the properties of the diamond film can be tailored. It varies from well-defined facets to irregular forms or round shapes. Variations in the diamond morphology with the substrate temperature are shown in Figure 10 for the DCTP jet. With increasing substrate temperature, it changes from predominantly more {111} to {100} facets, which was also found for an RF-ICTP Jet [80] and for DCTP CVD [81]. The crystallite size also increases with increasing substrate temperature [81-86], as is shown in Figure 10. However, the mechanism of diamond growth is very complex, and contrary results were also published [87]. Therefore, the substrate temperature must be kept constant during the deposition time and must be as uniform as possible across the entire surface area to minimize or prevent radial variations in the morphology of the crystallites. In the thermal plasma jet diamond CVD the substrate must be intensively cooled. Special designs of substrate holder exist [88], [89] by which either the different thickness or/and the varying materials influence the heat transfer to the cooling fluid (water is mostly used, but also ethylene glycol). To adjust for varying heat fluxes from the plasma jet to the substrate, special cooling systems have been developed [90], [91].

Figure 10. Morphology of diamond films manufactured with a DCTP jet and 5 vol % CH_4 in H_2 at various substrate temperatures

a) 780 °C; b) 850 °C; c) 950 °C; d) 1050 °C

The Role of the CH_4/H_2 Ratio. The morphology and therefore the quality of the diamond films depend on the ratio of the precursor dilution in hydrogen. The morphology can be changed in a similar way as for the substrate temperature with an

increasing methane/hydrogen ratio (Fig. 11). The ratios vary considerably with the deposition method used. The ratios of more than 5 vol % given in [76], [91], [92] are relatively high compared to those reported in [93-95] with less than 5 vol %. For epitaxial growth [96] or with nonthermal plasma techniques, concentrations of less than 1 vol % CH_4 based on the H_2 content are used.

Figure 11. Morphology of DCTP diamond films at varying volume content ratios of CH_4 to H_2 at a substrate temperature of 1050 °C

a) 4 vol % CH_4; b) 5 vol % CH_4; c) 7.5 vol % CH_4; c) 10 vol % CH_4

Precursors and Substrates. A wide variety of precursor and substrate materials has been tested. Methane has been most frequently used as precursor material. Other carbon-containing substances [97], [98] such as aliphatic and aromatic hydrocarbons, alcohols, amines, ethers, are also used:

1. Gaseous
    a. Methane
    b. Ethane
    c. Ethylene
    d. Acetylene
2. Liquid
    a. Methanol
    b. Ethanol
    c. 1-Propanol
    d. 1-Butanol
    e. Acetone
    f. Benzene
    g. Cyclohexane
3. Halogenated
    1. Dichloromethane
    2. Trichloromethane
    3. Carbon tetrachloride
    4. Trifluoromethane
    5. Tetrafluoromethane

More recently, halogenated hydrocarbons have been recommended, mainly because of indications of enhanced diamond nucleation density [99] and lower substrate temperature [100]. Substrate temperatures below 300 °C are possible. An overview on halogenated precursors is given in [101], [102]. However, the use of fluorine restricts the choice of substrate materials; for example, silicon is always damaged, even if only a small amount is added. Chlorine-containing compounds prohibit the use of stainless steel vessels.

The variety of substrate materials used are listed in in the following:

1. Carbons
    a. Amorphous carbon
    b. Graphite
    c. Diamond
2. Metals
    a. Aluminum
    b. Titanium
    c. Molybdenum
    d. Nickel
    e. Copper
    f. Tungsten
    g. Tantalum
    h. Platinum
    i. Germanium
    j. Iridium
    k. Silicon
    l. Tool steel (with interfacial stainless steel layer)
3. Ceramics
    a. Boron carbide
    b. Cubic boron nitride
    c. Silicon carbide
    d. Silicon nitride
    e. Titanium carbide
    f. Zirconium carbide
    g. Hafnium carbide
    h. Chromium carbide

i. Molybdenum carbide
j. Cemented carbide, such as WC – Co compound
k. Alumina
l. Silica

4. Polymers
   a. Polyimide (with interfacial layer)

Materials which easily form carbides are particularly suitable for diamond deposition. Due to the high solubility of carbon in tool steel, interfacial layers have to be deposited, such as tungsten or silicon carbide and silicon nitride.

Silicon single crystals, commonly taken from the microelectronics industry, are the most frequently used substrate materials in laboratory reactors. However, well-adhering, high-quality diamond films are necessary to realize coatings on industrially important substrate materials, such as ceramics, steels, nickel alloys, cemented carbides, and most alloys containing transition metals. Basically, all samples are diamond-ground and washed with alcohol in an ultrasonic bath. Different pretreatments have to be performed on these as-ground substrates to enhance nucleation and adhesion. Chemical and mechanic pretreatments increase the surface roughness, which improves both the nucleation density and the mechanical anchoring of the film. A review on different chemical and mechanical pretreatments is given in [103], especially for cemented carbides.

Another means to improve the nucleation density is a secondary discharge to the substrate. It is used to enhance the chemical nonequilibrium in the boundary layer in front of the substrate. In this way, the substrate can be cleaned when negative biased. The diamond growth rate is improved by positive biasing [104] due to the increased flux of atomic hydrogen to the substrate surface.

2.3.3. *Diamond CVD Techniques*

Today a wide range of methods exists to prepare CVD diamond layers. The techniques can be categorized according to the specific method of producing chemically active species, such as thermal decomposition, hot-filament technique, combustion process, plasma-assisted processes, and beam technologies (Fig. 12). The plasma-assisted processes include nonthermal plasmas, such as the direct current (DC) glow discharges, capacitively and inductively coupled 13.45 MHz radio frequency (CC- and IC-RF) plasmas, microwave (µW) plasmas excited by 915 MHz and 2.45 GHz radiation, as well as thermal plasmas (TP), such as the thermal inductively coupled radio frequency plasmas (IC-RFTPs) or thermal direct current plasmas (DCTPs) which produce plasma jets with high velocities and temperatures.

Figure 12. Diamond CVD technologies (from [97])

Beam technologies, such as electron or ion beams, and lasers are not often used for CVD diamond film production. Initially, thermal decomposition was used for diamond film production. The gas and substrate temperatures must be high enough to decompose the precursor gas molecules, and the resulting growth rates are too low to be industrially interesting. Therefore, plasma CVD methods were developed. Energy transfer from activated species of the plasma to precursor molecules leads to their decomposition and to chemical reactions already in the gas phase. In this way the deposition rate can be enhanced without increasing the substrate temperature.

2.3.3.1. *Nonthermal Plasma CVD*

Plasmas generated under high vacuum conditions are characterized by different temperatures of electrons and heavy particles such as ions, atoms, molecules, and radicals [105]. The low pressure is tantamount to low number densities. The long mean free path enables the electrons to gain high energies, but energy transfer to the heavy particles is reduced due to the low collision probability. Therefore, plasmas at pressures lower than 0.01 MPa are no longer in thermodynamic equilibrium. Such plasmas have the advantage of a large and homogeneous plasma volume; the disadvantages are the low gas velocities, thick boundary layers in front of the substrate [106], and medium growth rates (see Fig. 13).

Figure 13. Linear growth rate of various plasma jet techniques in comparison to other techniques, such as HF (Hot Filament), MW (microwave), RF and DC (radio-frequency and d.c. nonthermal plasma processes)

The *2.45 GHz microwave discharge* was the first and is still most frequently used diamond CVD technique with plasma discharge. An overview on the different microwave reactor types used for diamond CVD is given in [107]. The NIRIM reactor type was the first reactor reported [108] and operates with a power of up to 1500 W and pressures typically below 1 kPa. The carbon-containing gas mixture consists of 1 % methane in hydrogen, and the growth rate is about 0.5 µm/h for substrate temperatures around 1000 °C. The main drawback of this reactor type is the smallness of the substrate, which is only 2 – 3 cm in diameter. In the dome-shaped bell-jar reactor [110], three-inch silicon wafers are coated with polycrystalline diamond

at substrate temperatures of 900 – 1000 °C, pressures of about 1 kPa, and 1 % methane in hydrogen gas at a growth rate of about 0.2 – 0.3 µm/h. ASTex improved and commercialized the bell-jar reactor in the 1990s for using four-inch-diameter substrates. The highest growth rate reached with a high-pressure microwave source (HPMS) reactor with 5 kW and about 10 kPa amounts to 14 µm/h. The drawbacks are connected with the 2.45 GHz frequency: the power density, plasma size, and therefore the diamond deposition rate are limited. Nonuniform temperature distributions and film thickness, as well as variations in phase purity are possible. Shifting to 915 MHz can help to overcome the power limitation and to increase the geometric uniformity.

On the basis of mathematical simulations, the more recently developed ellipsoid reactor [109] for large-scale diamond film production was designed. A variety of different reactor sizes and designs have been explored, especially for 915 MHz. The plasma has the shape of a hemisphere sitting on the substrate. The design was commercialized by the AIXTRON Company. By using the AIX P6 (6 kW; Fig. 14) at 2.45 GHz and, in particular, the 915 MHz AIX P60 (60 kW) [111], free-standing polished diamond windows up to six inches in diameter (Fig. 15) can be produced with a maximum growth rate of 12 µm/h at a maximum pressure of 20 kPa.

Figure 14. Ellipsoidal microwave reactor AIX P6 [111]

Figure 15. Optical-window-quality free-standing diamond films [110]

As is shown in Figure 13, the growth rate can be increased also in the lower pressure region by means of *DC supersonic jet synthesis* [112]. Here a distinction is made between the DC plasma jet, which is more or less a thermal plasma jet, and the DC supersonic jet, which is also arc-heated but has a large deviation from thermodynamic equilibrium. Typically, the arc is generated inside a torch, similar to a DC plasma torch. The jet leaves the converging/diverging nozzle (Fig. 16) with a minimum diameter of about 1 mm in the reactor chamber, maintained at a pressure of 2 – 3 kPa [113], which is much lower than that in the torch (ca. 0.6 MPa). The high pressure difference is responsible for the gas dynamic conversion of thermal arc energy into high kinetic energy of the jet, which expands into the reactor with supersonic velocities (1 – 10 km/s) [114]. The temperatures in the jet are not higher than 2 kK, and reach the highest values of up to 5 kK in the bow shock near the substrate [115]. This kind of jet shows a large deviation from the local kinetic and chemical equilibria. The high flow velocities lead to small transport timescales relative to the chemical kinetic timescales [116]. Therefore, the recombination of atomic hydrogen is reduced and the carbon-utilization rate is high. The growth rate ranges between 6 [117] and 10 µm/h [118], which is much higher compared to the other nonthermal plasma techniques operating in the same pressure region (see Fig. 13). This results from the thinning of the boundary layer thickness due to the high flow velocities.

Figure 16. Schematic of the supersonic DC jet torch [115]

2.3.3.2. *Thermal Plasma Diamond CVD*

A promising alternative to the conventional low-pressure gas discharges is the use of high-pressure thermal plasma jets. Plasma jets are generated by electric discharges at moderate to high pressure (10 – 100 kPa and higher), so that the plasma leaves the nozzle with both high temperature (> 6 kK) and high velocity (often > 500 m/s). Due to the high plasma temperatures, the reactant decomposition process is much more intensive. All of the molecular hydrogen is dissociated into atomic hydrogen, the most important precursor in the diamond deposition process. The delivery of the atomic hydrogen to the substrate is enhanced because of the reduced thickness of the boundary layer due to the relatively high gas velocities. Thus, the highest growth rates are obtained with thermal plasma jets, as is shown in Figure 13.

The plasma jets can be categorized in accordance with the method by which the electric discharge is sustained. The radio frequency inductively coupled discharge and the direct current discharge, shown schematically in Figure 17, are the most frequently used plasma jets.

Figure 17. RF-ICTP jet and DC-TP jet

The radio-frequency inductively coupled thermal plasma (RF-ICTP) is an electrodeless plasma and is therefore almost free of contaminants. Two separate gas flows are necessary for maintaining the RF discharge: the sheath gas for discharge stabilization and for preventing direct contact between the plasma and the plasma-confining wall, and the central gas flow for the working gas. The features of the RF-ICTP are the large volume, and consequently the low flow velocities of the plasma exiting the torch, with or without a nozzle. The diameter of the plasma jet leaving the torch ranges from about 30 [119], [120] through 76 [121], up to 100 mm [122], depending on the torch geometry [124] and the reactor pressure [125]. The velocities at the nozzle exit decrease with increasing diameter and range from 30 m/s [126] up to 250 m/s [127]. Supersonic plasma jets generated by RF-ICTP with converging/diverging nozzles are also possible [128]. An other feature of the RF-ICTP is the possibility for axial precursor injection by means of a water-cooled feeding probe. Moreover, there are no restrictions on the kind of gases used.

The direct current thermal plasma (DCTP) is generated in a nontransferred plasma torch by the high-current arc generated between the cathode, usually made from tungsten, and an anode shaped as a nozzle. The nozzle diameter ranges from 3 to 8 mm, depending on the power level used. The argon – hydrogen gas mixture is heated by the high-current arc and leaves the anodic nozzle as a currentless plasma jet with a much higher velocity in comparison to the RF-ICTP jet [119], [120]. Impinging onto the surface, the DCTP jet also provides a higher momentum. However, the small diameter of the DCTP leads to small deposition areas. The deposition on extensive or three-dimensional substrates requires movement of the substrate. In contrast to the RF-ICTP torch, precursor injection must occur outside of the torch to prevent contamination of the tungsten electrode by carbon.

The main differences between the DCTP jet and the RF-ICTP jet are the temperature distributions in the axial and radial directions. The DCTP jet has steep gradients in both radial and axial directions. In the case of the RF-ICTP jet, the temperatures in both the axial and radial directions decrease much less within the plasma core than in the thermal DC plasma jet. The most important difference between the DCTP and ICTP jets is the thickness of the boundary layer in front of the substrate. In general, the boundary layer thickness of the ICTP jet is on the same order of magnitude as in the low-pressure plasma techniques. The higher the velocity of the jet impinging the substrate, the thinner is the boundary layer. In the case of the DC plasma jet, the boundary layer extends only to few tenths of millimeters. Therefore, chemical reactions cannot occur inside the boundary layer (“frozen” chemistry). Thus, the high temperatures at the end of the boundary layer of about 4000 K generate a lot of atomic hydrogen and carbon. Therefore, atomic carbon is the most important species for diamond deposition with the DCTP Jet [106].

The experimental set-up for Plasma Jet Diamond CVD (Fig. 18) consists of the plasma torch with its power supply, the gas supply with mass flow controllers for exact control of the gas flow and composition, the reactor chamber, the control unit for cooling water, and the automatic registration unit for plasma parameters (chamber pressure and substrate temperature, measured by a thermocouple in the substrate holder and by a pyrometer on the substrate surface) [129].

2.3.3.3. *Other CVD Techniques*

The *hot filament* deposition method is a simple technique and is therefore widely used. The principal task of the hot filaments is to dissociate molecular hydrogen into atomic hydrogen. Bare metal wires generate atomic hydrogen more efficiently than silicon carbide filaments. Atomic hydrogen is generated by thermal dissociation of molecular hydrogen at the hot solid filament surface. The upper operating temperature (ca. 2200 °C) of the filament restricts the quantity of atomic hydrogen produced. To overcome this, low pressures (e.g., < 10 kPa) are used to enhance its production and transport to the substrate. The substrate distance is relatively small (ca.1 – 20 mm). However, the low gas-phase concentration permits only relatively low growth rates compared to the plasma jet techniques (Fig. 13). Because of its low cost and its very simple construction, the hot filament process has been the most frequently used method since it was first reported [130]. The methane content based on the flow rate of molecular hydrogen is always less than 5 % [131]. A higher methane content lowers substantially the rate of recombination of atomic hydrogen at the substrate surface. Besides the relatively low growth rate, another drawback is filament recrystallization due to exposure to the carbon-containing atmosphere. The wire materials, such as tungsten and tantalum, change their structure as a result of carburization and hydrogen embrittlement. Cracks are formed, and the lifetime is limited to about 20 h, depending on the operating temperature [132]. Rhenium filaments allow carbon to diffuse rapidly through them without forming carbides. Carburized rhenium is ductile [133] and therefore has a longer lifetime. Single filaments are often used in laboratory reactors; multifilament reactors are more common for industrial applications. An overview on the hot filament process and scale-up for industrial purposes (see Fig. 19) is given in [134].

Figure 19. Drill bits in a hot filament reactor [135]

The *oxy-acetylene combustion flame* method was first used in 1988 [136]. The mechanism of diamond growth in combustion CVD is similar to the other diamond deposition systems, even though the composition of acetylene flames differs much from the common CH_4/H_2 mixtures. The combustion flame is divided into three regions: the inner flame, the acetylene feather, and the outer diffusion flame. The substrate is placed in the acetylene-rich feather region. The ratio of acetylene to oxygen is the most important parameter for diamond growth. At values of unity, the acetylene burns completely. Heat and atomic hydrogen are provided by the chemical energy of the oxidation of acetylene. A certain supersaturation of acetylene is essential. The highest diamond quality is obtained in a slightly rich acetylene flame with a supersaturation of up to 15 % (Fig. 20). Combustion CVD is possible at atmospheric pressure and reduced pressure. The lower the pressure, the lower is the growth rate. The growth rate at atmospheric pressure is about 40 µm/h, and at 6 kPa about 4 µm/h. Different types of burners are used. More recently, flat-flame burners with a uniform axial gas velocity have been used to enhance the deposition area while simultaneously improving the film uniformity [137]. Material deposited by combustion CVD has not been tested extensively. However, the quality is similar to that produced by hot filaments or plasma systems. There are not so many applications. Deposition onto steel has been tested with nitrided chromium as buffer layer [138]. Combustion CVD necessitates lower investment costs compared to the plasma CVD processes, but these saving are overridden by the high running costs due to the high quantities of acetylene and its relatively high costs.

3. Graphite

Otto Vohler, Gerd Collin, Ferdinand von Sturm, Erhard Wege

Graphite has been used for the production of refractory crucibles since at least the 15th century, and for pencils since about 1550. It was frequently mixed with optically similar minerals such as galena, molybdenite, and even lead (lead pencil). ABRAHAM GOTTLOB WERNER (1750 – 1817) named it after the Greek word " Γ ρ α φ ε ι ν" (to write). Since then, the history of graphite has been closely associated with the development of electricity. Sir HUMPHRY DAVY, in 1800, was probably the first to use carbon electrodes for his studies on the electric arc. The increasing demand for electric arc light carbons since about 1870 gave rise to several processes for the manufacture of artificial carbon (CARRÉ, BRUSH, SIEMENS). At the beginning of the 20th century, important electrolytic and electrothermic processes using carbon or graphite electrodes became available, e.g., aluminum electrolysis (HALL, HÉROULT), alkali–chlorine electrolysis (CASTNER et al.), calcium carbide (WILLSON), electric steel (HÉROULT), and silicon carbide (ACHESON). Progress has been made in customizing the carbon and graphite grades and increasing their usefulness for new and more rigorous applications.

3.1. Single Crystal

The ideal crystal lattice of hexagonal graphite is illustrated in Figure 21. Each carbon atom has three nearest neighbors within the layer plane at a distance of 0.1421 nm and a bonding angle of 120° [140]. Within the layer planes, the bond energy due to the trigonal sp^2 hybridization of the bonding orbitals is far greater than that of the nonhybridized orbitals which form weak π-bonds vertically to the layer planes. The layer or basic planes of the hexagonal modification are stacked in the sequence ABAB..., and those of the rhombohedral modification are in the sequence ABCABC... . Natural graphite normally contains both modifications, in some cases up to 30 % of the rhombohedral modification. The proportion of this modification may be increased by milling and shearing and decreased by thermal annealing. The space groups of the graphite modifications are D^4_{6h} – $P6_3/mmc$ and D^5_{3d} – $R\bar{3}m$, respectively.

Figure 21. Lattice of the cubic diamond and the hexagonal graphite crystal

The interlayer spacing depends on the degree of disorder and amounts to 0.3354 nm in an ideal crystal, 0.344 nm for crystals with a completely random stacking sequence (turbostratic structure), and even more for less ordered structures. One indicator of the disorder is the width of the X-ray diffraction lines. Most theories explaining the broadening are based on the assumption that aligned layer stacks only correlate in parallel. The broadening is then due to translation and rotation of the layers [141-143].

Other models only accept translations parallel to the layer planes, caused by clusters between the layers and larger vacancies within the layers [144]. These defects yield to deformations of the layers and deviations from the ideal AB sequence, respectively. Due to their layered structure, all vectorial properties are to a large extent controlled by direction. Some properties of single graphite crystals, their dependence on the crystal direction, and for reasons of comparison, some common properties of diamond are shown in Table 3. The anisotropy of thermal expansion is particularly remarkable since the crystal expands in the *c* direction and contracts in the *a* direction at temperatures below 400 °C. Parallel to the basic planes, graphite is a metallic conductor whose resistivity increases with rising temperature. In the *c* direction, graphite behaves like a semiconductor. The thermal conductivity strongly decreases with lower temperature. At room temperature, the conductivity in the *a* direction is better than that of copper. The properties shown in Table 3 strongly depend on the type of samples; therefore the original publications or manuals should be consulted for a deeper understanding [145-149].

Table 3. Properties of graphite and diamond (single crystals)

	Graphite		Diamond*
	***c* direction**	***a* direction**	
Density, g/cm^3	2.266		3.515

Mohs hardness [148]	9	0.5	10

* The properties of diamond crystals vary considerably

3.2. Natural Graphite

Occurrence and Properties. Numerous hypotheses on the genesis of natural graphite existed, but today most of them are forgotten. It is currently supposed that organic matter was the origin of most natural graphites with the probable exception of the Sri Lanka deposits. Graphite inclusions in plutonic rocks can be traced back to the accumulation of insoluble carbon within the residual melt. The decomposition of inorganic compounds, e.g., carbide, carbonyl, and cyano compounds, is less important for the genesis of graphite deposits.

Crystallinity, refractoriness, and other properties of natural graphite from different deposits may vary enormously due to differences in the precursor materials and the conditions of metamorphosis. In general, natural graphite is a ductile soft mineral which easily cleaves parallel to the basic layer. The flaky grades (plumbago or vein graphite) show a typical metallic luster; the microcrystalline “earthy” grades have a duller black appearance. Table 4 shows a classification [150], [151]. The most common accompanying minerals are quartz, mica, and feldspars; accessory minerals may include pyrite, magnetite, pyrrhotite, and calcite.

Table 4. Classification of natural graphite

	Deposit	Carbon content, %	Average crystallite diameter, mm	Origin
Macrocrystalline flakes	Brazil Federal Republic of Germany (Kropfmühl) China Finland Malagasy Republic Norway Zimbabwe Russia South Africa Czechoslovakia	< 60	< 0.1	syngenetic cata- and mesozonal metamorphism of sapropelites

Macrocrystalline lumps	Sri Lanka	< 100	< 0.01	epigenetic, probably pneumatolytic
Mesocrystalline	Austria Czechoslovakia	30 – 90	< 0.001	syngenetic metamorphism of sapropelites
Microcrystalline	China Italy Korea Mexico Austria	30 – 90	< 0.001	syngenetic, epizonal metamorphism of coals

Mining and Concentration. Natural graphite is mined in open-pit and underground mines. The crude ore contains several impurities in various quantities. Only some of the Sri Lanka deposits contain types with carbon contents up to 100 % [152].

The crude ore is separated in some places by hand. Crude ores with a carbon content sufficiently high for industrial use are only crushed, dried, graded, and if necessary, milled. Flake graphites must be enriched, preferably by using flotation processes. Since graphite flakes float easily, this process is successfully used even for low-grade ores. A modern flotation plant is illustrated in Figure 22.

Figure 22. Flow sheet of a flotation plant (Kropfmühl, Germany) [151]

a) Crusher; b) Silo; c) Rod mill and bowl classifier; d) Flotation cells; e) Grinder; f) Centrifuge; g) Drier

The separation of microcrystalline crude ore is more complicated. Since graphite and mineral impurities are intensively intermingled the separation is accomplished only after the crude has been finely ground. During flotation, the graphite-containing foam is possibly polluted by hurled mineral particles. Only if grain size, flotation agents, and other process parameters completely correspond to the properties of the crude ore is enrichment possible. It is reported that by using tar oil, pine oil, or float oil as a flotation agent and a water glass as a trigger for the nongraphitic components in a process including four flotation steps, microcrystalline graphite with more than 92 % carbon has been extracted [153]. Other proven flotation agents are petroleum, paraffinic oils, cresole, creosote oil, and aromatic amines.

Carbon enrichment by flotation yields up to about 96 % C for flake graphites. The mineral components of graphite may be further reduced if the graphite is purified by treatment with hydrofluoric acid, smelted sodium carbonate, or chlorine and fluorine at temperatures up to 3000 °C. The ash content can be reduced by this processes to less than 50 mg/kg [154], [155].

Uses. Natural graphites vary widely in flakiness, refractoriness, toughness, durability, bulk density, etc. and meet the requirements of various processing industries: 24 % are used in foundries, 24 % in the steel industry, 15 % for the production of crucibles, 12 % in the electrical field, 8 % in the refractory industry, 5 % for lubricants, 4 % for pencils, and 3.5 % for batteries [156].

Graphite crucibles are used in foundries for melting steel, nonferrous metals, and precious metals. The most suitable are clay-bound crucibles containing flake graphite grades with a carbon content above 85 %. Bricks for open-hearth furnaces [157], ladle plugs, and tape spouts are other examples for the use of natural graphite in metallurgy. When compared with other refractory materials, graphite-containing grades have generally better thermal conductivity, thermal shock resistance, and resistance against corrosion. Clay-bound graphite crucibles have been widely substituted by pitch-bound silicon carbide–graphite crucibles.

In the production of dry cells and storage cells, graphite powder is mixed with the active mass to increase the electrical conductivity. The conductivity of natural graphite powder is also used in plastics (against static charge buildup), explosives (against ignition by friction), and conductive lacquers.

Natural graphite is used to a large extent as a lubricant. Fine-grained graphite powders often having a particle size less than 1 µm are suspended in liquid carrier mediums, such as oils, greases, alcohols, or water. Most self-lubricating bearings and packings contain natural graphite as a lubricant; pencils function due to the gliding and lubrication of their graphite component. Other applications that use these properties are the smoothing of the surface of molds to facilitate the removal of castings after cooling, blackwashes, and additives decreasing the friction during the compaction of powders.

Natural graphite is also used for carburization, deoxidation, and the covering of metal melts. Plastics, ceramics, porcelain, and concrete are colored with graphite, particularly with microcrystalline grades, and it also serves as a pigment in temperature-resistant paints. Well-crystallized flake graphites are a precursor for graphite intercalation compounds,

expanded graphite, and graphite foils (see Sections Graphite Compounds and Expanded Graphite and Graphite Foil Derived from Intercalation Compounds).

Purified flake graphite has been proposed as a moderator and reflector material for nuclear fission reactors [158]. To some extent, natural graphite is used for the production of fuel elements for high-temperature nuclear reactors [159].

The world production of natural graphite amounts to about 500×10^3 t [156]. The most important countries mining graphite are the following:

flaky graphite grades: Former Soviet Union, China, Malegasy, Sri Lanka, Germany, and Norway
earthy graphite grades: Korea, Mexico, and Austria.

3.3. Artificial Graphite

In general, artificial graphite is produced by heating carbon compounds or carbon powder to 2500 – 3000 °C [160], [161]. This treatment increases the structural order, depending on the structure of the precursor materials. One distinguishes between soft (or graphitizing) carbons and hard (or nongraphitizing) carbons by the fact that the preordering of the first type is distinctly better than that of the last. Examples of both types are petroleum coke and charcoal, respectively. Usually, any carbon material heated above ca. 2500 °C is designated as an artificial graphite, irrespective of its real crystal structure. The thermal graphitizing process can be accelerated by catalysts. Although catalytic graphitization had already been studied by ACHESON, it is of little practical significance. Other methods for the production of artificial graphite are the vapor deposition of volatile carbon compounds or the condensation of carbon vapor (pyrographite) [162], crystallization of carbon melts at pressures above 15 MPa [163], precipitation from oversaturated metal melts (kish graphite) [164], the decomposition of carbide crystals and nitrogenation of calcium carbide [165], as well as the electrolytic decomposition of carbonate melts [166]. All of these processes are economically less significant than thermal graphitization.

All carbon-containing materials are, in principle, suited as a raw material for the production of carbon and graphite. In the first step, the raw material is decomposed by pyrolysis, and in the second step, the intermediate carbon product can be graphitized by further heat treatment. During pyrolysis, the intermediate material may be solid, liquid, or gaseous; it is obvious that the mobility of the molecules determines the degree of microstructural ordering.

It is, therefore, customary to distinguish between solid-, liquid-, and gas-phase pyrolysis, although transitions between the pure reaction types exist. Examples of the *solid-phase pyrolysis* is chars and vitreous or glassy carbon which is produced by pyrolysis of cross-linked polymers. Due to the structural disorder and the small average crystal size of these polymers, the ability of these materials to be graphitized is low. The precursor material of carbon fibers, e.g., thermally stabilized polyacrylonitrile or pitch, also does not melt during pyrolysis, but an ordered microstructure is achieved by stretching the fibrous material below the pyrolysis temperature and preserving this degree of order by the above-mentioned stabilization treatment [167].

An example of *liquid-phase pyrolysis* is petroleum coke, which is the most important raw material for the manufacture of carbon and graphite products. BROOKS and TAYLOR first discovered the formation of optically anisotropic spherulites (mesophase) during the pyrolysis of petroleum pitch, coal tar pitch, and softening coal [168]. During heat treatment, pitch gradually forms an isotropic melt and develops small spherulites with increasing temperatures, probably by a process of homogeneous nucleation, the diameter of which increases with temperature and to a lesser extent with residence time. The spherulites are nematic liquid crystals composed of large lamellar aromatic molecules. The isotropic phase is finally exhausted, and the spherulites touch each other and coalesce. Formation and structure of mesophase are essentially governed by three limiting conditions:

1. the shape of the primary molecules must favor the formation of liquid crystals
2. the fluidity of the system
3. the reaction or condensation rate must be smaller than the ordering rate

Other factors influencing the structure of the mesophase which eminently affects structure and properties of coke materials are the amount of nonmelting constituents and/or impurities [169].

The chemistry of the pyrolytic conversion of hydrocarbon compounds to solid carbon involves numerous chemical reactions. Generalized schemes have been developed by studying simpler models [170], [171]. The major reactions involved are:

bond cleavage and formation of free radicals
molecular rearrangement
thermal polymerization
aromatic condensation
elimination of side-chains and hydrogen

A general scheme is shown in Figure 23 with structural models of the reaction products. Due to the formation of volatile products during pyrolysis and structural transformation, pores and shrinkage cracks develop on solid carbon. Carbon must be heated to ca. 3000 °C to be transformed into graphite. The degree of graphitization, which is an indication for a perfect graphite crystal, the spatial distribution of the crystallites, and the amount and distribution of porosity determine the properties of the final product. Lattice disorder as well as porosity can be reduced by high-pressure treatment at temperatures above 2500 °C [172].

Figure 23. Reaction scheme for carbonization and graphitization

Gas-phase pyrolysis is characterized by thermal cracking of gaseous hydrocarbon compounds and deposition of carbon on a substrate. Examples are pyrocarbon (see Section Pyrocarbon and Pyrographite), carbon films, and carbon black. Stress annealing of pyrocarbon at high temperature yields nearly perfect graphite crystals.

[Top of Page]

4. Carbon and Graphite Materials

Gerd Collin, Ferdinand von Sturm, Erhard Wege, Wilhelm Frohs

Most artificial carbon and graphite materials were developed in response to the growing demand for high-temperature electrodes and corrosion resistant materials.

DAVY employed carbon electrodes cut from charcoal for his electric arc studies (1801). FOUCAULT prepared electrodes from retort carbon which is deposited on the upper parts of the retorts during the production of coke and water gas (1844). Since these products were far from uniform the next step was to improve uniformity by applying powdered carbon as a raw material, e.g., caking coals, powdered coke, retort carbon, and lampblack (SCHOENBEIN, BUNSEN 1840 – 1842, STAITE, EDWARDS 1846, LEMOLT 1849, CARRÉ 1867). The powders needed to be bound with a carbonizable binder, e.g., concentrated sugar solutions or tar. In 1876, BRUSH introduced petroleum coke, which is now the most important raw material due to its uniformity and graphitizability.

DESPRETZ (1849), BERTHELOT (1870), and MOISSAN (1890) discovered the transformation of carbon into graphite when carbon is heated in an electric arc. GIRARD and STREET (1893) attempted to graphitize carbon rods by using this treatment.

The first useful processes for graphitization based on direct resistance heating of the artifacts were proposed by CASTNER (1895) and ACHESON (1895).

Carbon and graphite materials are characterized by their thermal and electrical conductivity, which resembles that of metals, and their thermal and chemical stability, which is similar to that of refractory materials. Their preferred applications are, therefore, high-temperature electrodes and conductors used in the presence of corrosive media and refractories with considerable thermal conductivity. When raw materials and process variables are changed, carbon and graphite products can be adjusted within a broad range to meet all usage requirements.

4.1. Carbon and Graphite Artifacts

4.1.1. *Manufacture*

Most methods for the manufacture of carbon artifacts consist of a two-stage process. In the first step, raw materials, especially coke, are produced by pyrolysis of carbon-containing substances, e.g., pitches and coals. In the second step, the unmeltable coke, together with a binder, is processed to carbon in a manner similar to the manufacture of ceramic materials. The carbon can be transformed into graphite by subsequent heat treatment.

Petroleum coke, pitch coke, metallurgical coke, anthracite, and carbon black are commonly used as raw materials. Coal tar pitches are the most commonly used binder material; less common are petroleum pitches and resins. Mixtures of these materials are shaped by extrusion, vibration molding, die molding, or isostatic molding and are baked at temperatures of ca. 1000 °C in an inert or reducing atmosphere and may be graphitized by further heating to 3000 °C. The manufacturing process is shown in Figure 24.

Figure 24. Carbon and graphite manufacturing, flow diagram

Raw Materials. The range of possible raw materials extends from well-ordered *natural graphites* and *needle cokes* with highly preordered two-dimensional layer stacks to less ordered materials such as *chars* and certain types of *carbon blacks.* The properties of carbon and graphite products and their performance depend to a large extent on the properties of the raw material. Therefore, the selection of raw materials is a very important step in the manufacture of carbon and graphite.

Petroleum coke, the most frequently used raw material, is produced from residues of atmospheric- and vacuum-distilled crude oil, from catalytically or thermally cracked fractions, and residues from the production of ethylene [173]. The principal method is the delayed coking process (⟶ Petroleum Coke). Some of this delayed coke is high in sulfur and metallic impurities and, therefore, is unsuited for the production of high-quality carbon grades [174]. Due to the increasing requirements for high-power graphite electrodes, the demand for well-ordered needle coke with an acicular or needle-like microstructure has increased. Needle coke precursors are the hydrodesulfurized more aromatic refinery streams [175] from

which the asphaltene components have been removed by cracking and distillation, e.g., decant oils derived from catalytic cracking processes [176], [177]. The shortage of suitable crude oils for the production of needle coke gave rise to more flexible processes with regard to feedstocks [178]. Coal tar pitches and coal extracts have also proven to be precursor materials for needle cokes [179], [180]. Graphite artifacts containing needle coke are characterized by outstanding thermal shock resistance and low resistivity.

Normal feedstock gives less anisotropic petroleum coke, which is used in large quantities for the production of carbon anodes [174]. Isotropic coke structures are obtained from feedstocks containing fast-reacting components [181]. Examples of isotropic coke types are gilsonite and fluid coke, a residue of a fluidized-bed coking process [182]. Isotropic cokes are of interest for nuclear reactor graphite grades.

Pitch coke, which is produced by coking of heat-treated or blown coal tar pitch, is less ordered than average petroleum cokes and has greater hardness and strength. Coking takes place in a chamber furnace or, more recently, in a delayed coker [183] for the production of needle coke from coal tar pitch.

Carbon black and *lampblack* are used predominantly as additives to increase bulk density, resistivity, and polishability of the carbon or graphite material. Brush grades may contain blacks exclusively. In such cases, the black is processed with a binder to an intermediate product called carbon black coke [184]. Additives for reducing electrical resistivity are artificial and natural graphite.

Metallurgical coke or *anthracite* are useful for the production of refractory linings (blast furnaces) and cathodes for aluminum production. Metallurgical coke is also used as a packing material in baking and in graphitization furnaces.

Calcination. Most raw materials, especially delayed-coking petroleum coke, must be calcined to decrease the volatile matter which forms during the baking process of the carbon material and causes severe shrinkage. During calcination, water and volatiles are removed by dehydrogenation and dealkylation; the coke attains its final porosity and its density is increased. The coke quality is determined by the maximum calcination temperature, calcination time, and the gaseous atmosphere during processing [185]. Even the thermal expansion of the coke is influenced by the calcination conditions, as a unique system of microcracks is developed which absorb, to some extent, the expansion of the crystallites; that results in a smaller expansion of the coke grains [186]. Maximum temperature of calcination is ca. 1200 – 1400 °C for petroleum coke and even higher for anthracite (electrocalcination).

Calcination is generally performed in rotary kiln furnaces consisting of a slightly inclined tube 2 – 3 m in diameter and 50 – 70 m in length. The residence time of the coke is ca. 2 h; the evolved volatiles are burned to deliver the energy required to raise the temperature of the coke and kiln to the calcination temperature. Within the last few years, the thermal efficiency has been improved so that additional energy is no longer needed. The kiln contains a cooling zone in which the calcined coke is cooled before discharging.

Rotary hearth furnaces are another furnace type used for coke calcination [187]. According to this process, the coke is heated on a disk that rotates slowly around a vertical axle. Vertical retort systems are of less significance.

If higher calcination temperatures are required, gas-fired furnaces may be used, but are less effective than electric calciners. These furnaces generate heat by resistance heating, which heats the carbon material to temperatures above 1600 °C. Most notably, anthracite is calcined by this process. A similar process has been proposed for the desulfurization of petroleum coke [188]. Properties of cokes are shown in Table 5.

Table 5. Properties of filler materials

	Needle coke	Petroleum coke (regular)	Pitch coke	Metallurgical coke
Microstructure	coarse fibrous	mosaic	coarse mosaic	heterogeneous, fine isotropic
Density (calcined at 1300 °C), g/cm^3	2.10 – 2.15	2.11 – 2.13	2.07 – 2.11	1.9 – 2.0
Ash content, %	0.05 – 0.3	0.1 – 0.3	0.2 – 0.4	7 – 11
Sulfur content, %	0.2 – 0.9	0.6 – 1.8	<0.6	<1.0
Coefficient of linear thermal expansion (measured with graphite rods, 20 – 200 °C), 10^{-6} K^{-1}	< 0.8	1.0 – 2.0	2.6 – 3.0	
Coefficient of volume thermal expansion, 10^{-6} K^{-1}	3 – 5	6 – 10	8 – 14	9 – 11
Anisotropy of thermal expansion	>2	1.5	1.4	1.2

Binder Materials. The purpose of binder materials is to wet the surface of carbon grains, give mixtures of high plasticity when mixed with grains, and give high-yield carbon residue after pyrolysis. Coal tar pitches, the residues from the distillation of crude tar produced while coking bituminous coal, are most suited. The distillation of tar is generally performed continuously in atmospheric columns and under vacuum. In special cases the pitch residue can be heat treated at about 400 °C to increase the content of quinoline-insoluble and toluene-insoluble matter, which influences the coking value and binding behavior [189]. The treatment is limited by the rising softening point. Characteristic properties of some pitch grades are illustrated in Table 6 (see ⟶ Tar and Pitch). Pitch grades with higher softening points are preferably used as binders for the production of molded graphite grades. The softening point represents a certain viscosity, but gives no information on the slope of the viscosity – temperature curve, an important factor for mixing and forming [190]. Since an increasing viscosity hampers flowability, the softening point of pitches used as impregnating agents should be lower than that of binder pitches. Another characteristic of pitches is their distillation curve, which should change only gradually. Petroleum pitches processed by dealkylation and dehydrogenation, with subsequent condensation and polymerization of low-boiling decant oils and aromatic extracts, have also been proposed as a binder and impregnating material [191]. Due to the lack of tar in the United States, petroleum pitches are widely used for impregnation.

Table 6. Properties of pitch binders and impregnants

	Binders for carbon anodes		Binder	Impregnating agent
	Prebaked	Söderberg	for graphite electrodes	
Softening point (Mettler), °C	110 – 130	110 – 130	100 – 115	65 – 90
Density, g/cm^3	1.32	1.32	1.32	1.25
Quinoline insolubles, %	6 – 10	6 – 10	6 – 10	< 5
Toluene insolubles, %	20 – 30	20 – 30	20 – 30	10 – 20
Coking value (Alcan), %	> 60	> 60	55 – 60	40 – 50

The coking value of pitch binders can be increased by adding condensation agents, e.g., sulfur, Lewis acids, etc. [192], [193]. To improve the flowability of the mixtures, lubricants are added that are insoluble in pitch such as oil, stearic acids, and metal soaps [194].

Thermosetting resins are also reliable binders and impregnating agents, although their use is limited to the production of smaller carbon and graphite shapes because of higher costs [195]. Phenolic and furan resins are frequently used.

Grinding and Sizing. The bulk density of carbon and graphite shapes depends on the porosity of the coke grains and the packing density of these grains [196]. These variables are controlled by crushing and grinding the coke and sizing the milled product. Large grains are generally used for the production of large shapes and smaller ones for small bodies. The maximum grain size is ca. 15 – 20 mm for large electrodes and less than 20 µm for spectroscopic carbon grades. The microstructure of the artifacts improves with decreasing grain size.

Unfortunately, the binder requirement increases with decreasing grain size, and higher binder contents imply problems during baking. This problem can be solved with a multistep process using pellets or agglomerates which are baked, partially ground, and again mixed with a binder whose proportion can then be relatively small. This process is also advantageous for controlling the anisotropy of the artifact, which is primarily determined by the shape factors of the coke grains [197],[198].

The calcined coke discharged from a silo is ground and sized in a highly automated process using roll crushers, roller pulverizers, as well as ball mills and jet mills. The product is sized by vibration screens, jarring screens, or separators. Pitch binders are usually melted, but the pitch may also be ground in swing-hammer mills.

Mixing. Mixing is generally performed at temperatures at least 50 K above the softening temperature of the pitch binder. The proportion of the filler material and binder determines the fluidity of the mixture, which also depends on the grain size of the filler material and the forming procedure. The average binder content is about 15 – 30 %. A green mixture consists primarily of filler, binder, and air bubbles [199]. During the mixing process, the bubbles must be removed and the binder should at least partly penetrate the pores of the coke particles. High mixing temperatures accelerate the spreading of the binder films on the solid surface [200].

The different filler materials stored in separate bins are discharged, weighed, and fed in the proper proportion to the mixer [201]. Before the filler is blended with binder, it is customary to homogenize the filler components and heat the filler to a temperature above the softening point of the pitch binder.

Kneaders with rotating sigma blades, ribbon blenders, and jet mixers, which are heated electrically, with natural gas, steam, or thermal oil, are customary. Mixing time is 20 – 60 min and the capacity of these mixers is 800 – 2000 L. Traditional sigma-blade mixers have been partially replaced by fast-running intensive mixer systems that allow mixing times of less than 15 min [202]. Continuous kneading extruders are used especially for the production of carbon anodes [203]. The homogeneity of the mix can be improved by using a vacuum or increased pressure [204]. Trapped air is removed and the impregnation of the porous coke particles increased. In another process, the filler is dispersed in a solution of binder material which is precipitated through addition of a further liquid in which the binder is insoluble and which is miscible in the solvent [205]. This process coats the particles with a uniform binder film.

If necessary, the lubricants are added to the mixture shortly before completing the mixing process. The mixture must be

cooled to the forming temperature in either hopper or barrel mixers, cooling drums, or conveyers. Mixing a liquid coolant, e.g., water, into the green mix and vaporizing the coolant results in a more uniform temperature distribution [206], [207]. Since this process can be carried out in a closed system, tar fumes are not emitted.

Forming. Due to the high production rate, elongated shapes are usually formed by *extrusion.* The cross-section may be circular, rectangular, or more complicated, e.g., for finned tubes. The cross-section ranges from a few square millimeters (battery carbon, spectroscopic carbon) to nearly 1 m^2 (electric furnace electrode). The hot carbon mixture is charged into the cylindrical chamber (mud cylinder) of a conventional hydraulic press [208], evacuated, and compacted. The mixture is forced through a forming die by an advancing ramhead or piston. The mixture may also be fed into the die by one or two augers. The mud chamber is up to ca. 1.5 m in diameter and up to 3 m in length, and the pressing force up to 60 MN. Auger extrusion allows a continuous extrusion process, but the extruded form often has a spiral internal structure. Although this structure may be destroyed by special gratings in the forming die to reorient the mix flow, this process is used only to form shapes of a small diameter [209]. Proposals for continuous piston extrusion have not yet been realized on a large scale [210].

The flow profile of the mixture also affects the structure of the forms including pore structure, anisotropy, and crack formation [211]. Even more important is the shape of the coke grains, which are aligned parallel to the flow lines. The structure and anisotropy can be controlled to a certain degree by changing the converging section of the die between the mud cylinder and the forming die [212]. The wall friction may be reduced by forcing lubricants through small openings in the wall [213]. For the production of tubes and other hollow bodies, a mandrel is positioned in the forming die.

The extruded form must be cut into sections of appropriate length. A cutting device which moves parallel and more or less synchronously with the formed body is used [214]. To avoid deformation, the bodies are cooled from the extrusion temperature (20 – 30 K above the softening point of the binder) to room temperature by spraying or dipping into water [215].

Molding. Smaller bodies, as well as some of the anode blocks used in the electrolysis of aluminum, are frequently produced by molding. Due to the smaller amount of binder, the shrinkage of these bodies can be better controlled and forming to the final size is possible (press-to-size). Pressures as high as 200 MPa (2 kbar) are necessary for compacting. The relationship of height to cross-section of the body is limited by the wall friction, which can at least be partly compensated by pressing at a temperature above the softening point of the binder or by adding solid or liquid lubricants. Crank, eccentric, and hydraulic presses are used, with the force of the press plunger reaching 140 MN.

As a consequence of the lower impact of flowability, the composition of the mix can be varied to a larger extent than in the extrusion process. Molding is, therefore, particularly well suited for the production of carbon and graphite bodies for such sensitive electrical and mechanical applications as brushes, electrodes for electric discharge machines, bearings, etc. For the production of larger bodies, this process must compete with isostatic pressing and especially vibration molding.

Isostatic Molding. In contrast to other forming methods, the compacting forces are transmitted by a fluid acting equally from all directions. Accordingly, the density gradient is smaller and the uniformity of the pressed form is better. The dies (bags) consist of an elastomeric material, e.g., silicon. They are usually evacuated during or after being filled with the pressing powder and are attached to the pressure tank (dry bag) or are freely removable (wet bag). The pressure tank is up to 1 m in diameter and more than 2.5 m in height. The pressure is up to 200 MPa (2 kbar) [216]. When the powder is being compacted, all anisometric particles are aligned perpendicular to the direction of force, yielding a quasiisotropic body. This is most advantageous for nuclear graphites, particularly spherical graphite forms containing nuclear fuel materials [217]. Compared to other forming methods, the overall anisotropy of the shape is small even when the pressing powder contains anisometric particles such as natural graphite or needle coke [218], [219].

Vibration Molding. During the last decades, the use of this method has steadily increased, particularly for the production of carbon electrodes used for aluminum electrolysis and the production of other large equipment containing coarsely grained carbon. A compacting machine consists of a vibrator and a mold which are connected. The damping capacity of viscous carbon mixtures is higher than that of dry granular materials. To achieve sufficient compaction, the pressing mixture must be loaded with top weights [220] and then evacuated [221]. The vibration frequency is ca. 1000 – 2000 cycles per minute, which may be changed eventually to compensate changing damping capacity during compaction. One advantage of this forming method is its great variability, which makes it possible to compact mixtures containing small as well as large amounts of binder. Even large cylindrical bodies can be formed [222]. A continuous compaction method for these bodies has been proposed. Molding vibrators are completely automated by using molds mounted on turning or pushing tables [223]. Jar molding, a vibration molding method with a low frequency but large amplitude, is used to form large-diameter carbon electrodes.

Other Forming Methods. Other methods are less common. Carbon shapes with a high bulk density can be produced by explosion impact [224] or by implosion into a mold [225]. Spin molding is used especially for mixtures containing clay for the production of graphite crucibles. A mold containing the mixture is rotated at a speed of several hundred cycles per minute while a plunger is moving axially into the mixture [226]. Tamping, a vibration molding with a low frequency, but large amplitude, is almost exclusively used for the compaction of carbon-containing cements used for joining carbon cathodes and carbon blocks.

Baking. In the baking process, the binder material of the shaped artifact is pyrolyzed, and a binder coke is formed which joins together any coke particles. Volatile products are generated which must be removed from the carbon form. The process consists of the following steps: (1) the heat transfer from the outside into the form, (2) the pyrolysis reactions, and (3) the removal of volatile products from the form [227]. Heat transfer and the diffusion of the volatile products developed during baking are influenced by layers of packing material — mostly granular metallurgical coke — needed to prevent deformation of the bodies at temperatures between the softening point of the binder and binder coke formation. The packing material also protects the bodies against oxidation. In addition to the mass loss, the bodies undergo complicated volume changes during baking which depend on the type and amount of the binder, the heating rate, and the volume of the body [228] (Fig. 25).

These changes, as well as pore formation, require certain heating programs to avoid crack formation which is detrimental to the quality of the product. The increase in temperature within the body should ensure that the transfer capacity of volatile pyrolysis products is larger than or equal to the quantity of products formed at each temperature interval. Since the formation rate of volatiles is largest in the interval between 300 and 500 °C, the heating rate in this range is as low as 0.5 – 4 K/h. At higher temperatures, considerably higher heating rates are tolerated. The final temperature lies between 750 and 1300 °C, depending on the further treatment of the form.

Figure 25. Variation in length and mass of pitch-bound carbon shapes during baking

At normal baking conditions, about 30 – 50 wt % of the original binder is lost as volatile products. This loss can be decreased by adding Lewis acids, sulfur, and other condensating substances to the binder [229], or by performing the heat treatment under pressure [230], [231]. Pressure baking not only increases the coking residue, but also cuts production time from weeks to minutes, thus enabling the automation of carbon production to a degree not attainable with other baking processes.

In general, all furnaces are suited for baking carbon bodies, provided the temperature is adjustable. Each furnace must have devices for collecting and purifying the volatile pyrolysis products, e.g., electrostatic precipitators or incinerators [232]. Ring furnaces, in which several chamber furnaces are coupled, are most frequently used for baking carbon bodies. For the baking of sensitive grades, e.g., large electrodes, single-chamber furnaces are customary. Tunnel kilns are only used for rebaking impregnated articles.

Ring Furnace. Ring furnaces consist of ca. 10 – 30 identical brick chambers or pits that are connected to each other to form an endless chain of individual units. A distinction must be made between open-top and closed chambers. In both types, several process steps occur simultaneously: one section of the furnace is loaded with green forms, in a second section the green forms are preheated by combustion or waste gases streaming in through flues located beside the chambers, in a third section the chambers are fired by gas or oil burners, in a fourth section the chambers are cooled by air streaming to the burners through flues, and in a fifth section the cooled baked forms are unloaded (Fig. 26). After a defined period of time, the burners are shifted to the neighboring chamber in the direction of the gas flow, the loaded chamber is coupled to the combustion gas stream, and the outermost chamber is unloaded. Ring-type furnaces, in which the heating section rotates stepwise through the furnace, are counterflow heat exchangers, which allow better fuel economy than other furnaces. To improve heat exchange, the flues contain baffles. In the closed-type ring furnace, the chambers are divided into subsections by hollow brick walls acting as flow channels. The temperature distribution within the chambers depends on a uniform gas velocity [233], [234]. The temperature adjustment is complicated since the burner and the suction cannot be individually adjusted. A more rapid cooling can be achieved without affecting the entire furnace by spraying water or vapor into one or more of the chambers [235], [236].

Figure 26. Closed ring furnace (schematically)

a) Unloading chamber; b) Cooling section; c) Heating chamber; d) Preheating section; e) Loading chamber

The baking cycle is relatively short if identical shapes are baked and thin layers of packing materials are used. These conditions are fulfilled by carbon anodes, for which a firing curve is shown in Figure 27. The capacity of large ring furnaces amounts to about 50×10^3 t/a.

Figure 27. Ring furnace, heating cycle [236]

Single-Chamber Furnace. Several different types, usually containing a square chamber, are in use. To improve gas circulation and heat transfer, some types are equipped with fire or flue pipes or with channeled walls [237]. Some furnaces are open, but most types are covered by arched covers. The green bodies are often transferred to steel saggars, which are distributed in the chamber according to a given pattern. The thickness of the packing mass layer between the saggar wall and the green form can be kept small, thus improving heat transfer and the adjustability of the system. This enables the baking of sensitive carbon grades.

The efficiency of single-chamber furnaces can be improved by using a chamber bottom which can be moved out of the furnace for loading and unloading (car bottom furnace, bulk furnace) [238]. For greater energy efficiency, two or more furnaces act together for recovering the heat of the combustion gas.

Tunnel Kiln. Tunnel kilns are used only for baking small carbon bodies and for rebaking pitch-impregnated carbon artifacts, although handling is simpler and the fuel efficiency obviously better. On the other hand, special precautions must be taken to

avoid condensation of the volatile pyrolysis products (especially tars) and to get a stable flow system from the flue gases. Therefore, the tunnel must be divided into several subsections [239].

Other Furnaces. Electric resistance heating (resistor baking) at high pressure remains of limited use [230]. The short baking cycle of a few minutes duration at pressures of ca. 500 MPa (5 kbar) is increased to several hours at pressures of ca. 0.5 MPa (5 bar) [240]. To overcome the considerable resistance of the green form, it is also possible to bake with convection heat and continue with resistance heating after some pyrolysis [241].

After the baking process, the adhering packing mass is removed from the baked shapes by cleaning machines.

Graphitization. Graphitization is the transformation of somewhat disordered carbon material into the well-ordered graphite structure; the heat treatment of carbon shapes at temperatures above ca. 2600 °C is referred to by this term. During this heat treatment, the average interlayer distance decreases and the height and width (L_a and L_c) of the ordered areas increase [242-244], whereby the attainable order or degree of graphitization depends on the structure of the precursor material. Structural ordering is a relatively rapid process (Fig. 28), while the rate of volume shrinkage decreases with increased heating [246]. All volume properties, such as bulk density, resistivity, strength, etc., depend not only on the maximum temperature, but also on the heating rate. The heating rate of larger specimens may be limited by insufficient thermal shock resistance [247]. The actual rate is shown in Figure 29. During heat treatment, the impurities within the artifacts react with the carbon to form carbides, which mostly decompose and vaporize at higher graphitizing temperatures.

Figure 28. Changing of interlayer spacing during graphitization [245]

Figure 29. Temperature cycles of the Acheson furnace (a) and Castner furnace (b)

At temperatures of ca. 1600 – 1700 °C, the sulfur contained in the carbon bodies is promptly emitted, thereby increasing its volume (puffing) [228]. To avoid the formation of cracks, puffing must be reduced by adding inhibitors such as powdered iron, iron oxide, or compounds of alkali and alkaline-earth metals which delay sulfur emission. Graphitization may also be performed at lower temperatures by adding carbide-forming elements to the green mixture, e.g., boron, silicon, iron, nickel, or vanadium; this is called *catalytic graphitization.* The different solubility of ordered and nonordered carbon in the carbide phase is the driving force [248], [249]. In practice, this process is discredited by the remaining carbide impurities and the formation of larger pores due to carbide decomposition.

The grade and rate of graphitization may be increased by viscous deformation of the carbon artifacts at temperatures above 2500 °C, known as “hot-worked graphite” [250]. Although the properties of these artifacts are promising, the process has not been introduced on a larger scale due to the great expense.

Graphitization is performed almost exclusively with Acheson and Castner furnaces. For the production of graphite electrodes, Acheson furnaces have been increasingly replaced by Castner furaces. Inductive and radiation heating is used only for the production of specialities.
